51 The Effect of Currents and Other Disturbing Factors upon the Rate of Absorption.

The discussion of the rate of absorption has thus far been based upon the assumption that the body of water in question is quiescent. The effect of departures from this assumption must now be considered. This brings up the question of currents, in the broad sense of the word, including eddies, tide and wave action and brief local disturbances such as are caused by passing vessels. More specifically it is the vertical components of these currents only that enter the problem, since these alone induce a vertical circulation. The effect of wind will be first considered.

52 Effect of Wind.

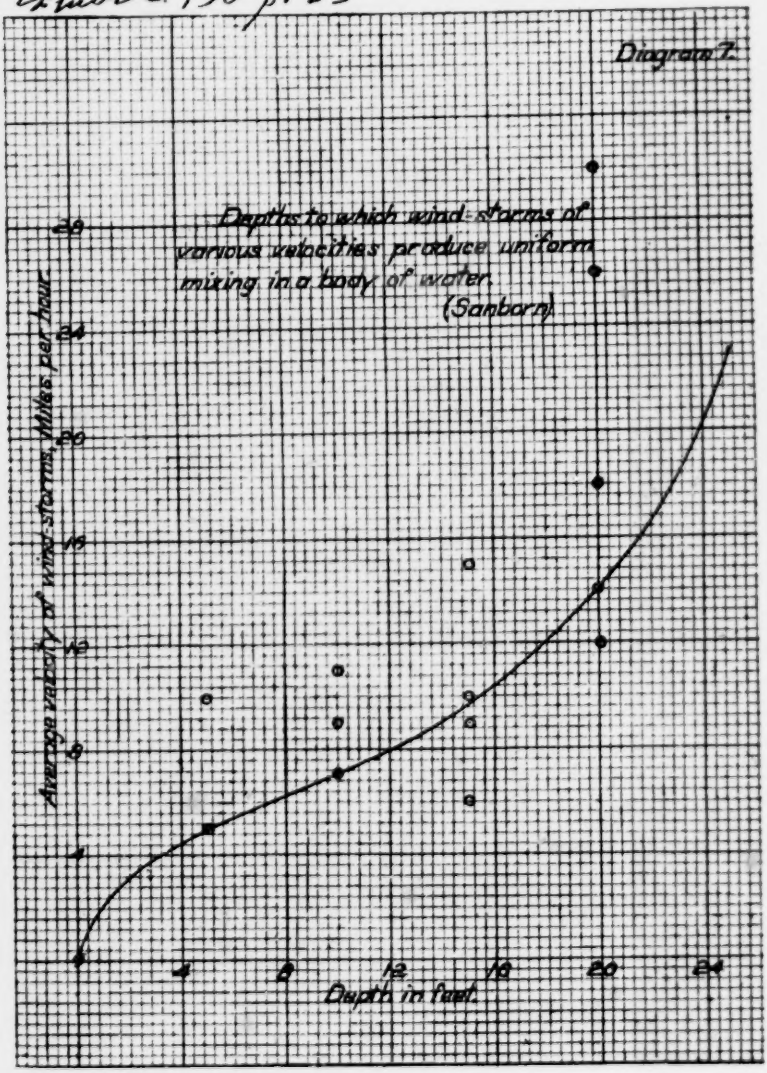
The wind is generally looked upon as an important factor in the aeration of water. The very obvious agitation of the surface, produced by moderate breezes, and the more violent effect of storms, would seem at first glance to lend strength to this view. More careful analysis, however, in the light of the theory of aeration which has been developed makes it possible to test this hypothesis and determine the manner in which wind action must affect aeration, if at all, and approximately at least, the extent of such effect.

Since the fundamental law of aeration is one of diffusion, and fruthermore, since the surface of any body of water is practically saturated at all times, it must be evident that no mere surface action can by itself affect the rate of diffusion. In order to assist the latter there must be an actual mechanical mixing of the water. If such mixing occurs to any given depth by reason of wind action the facts which have been developed thus far permit the following quantitative analysis to be applied.

It has been seen that a body of water starting with a uniform initial concentration of oxygen, B, less than saturation will absorb oxygen, and that by diffusion a concentration gradient is established, from saturation at the surface to the value, B, at some depth within. This process is continuous, but the rate of absorption is a constantly decreasing one. Starting with a condition of uniform mixing the absorption per hour is a maximum at the start and decreases steadily, as is shown in Table No. 3, and more strikingly in Diagram 8.

The immediate effect of wind upon a body of water is to produce wave action. A definite relation exists between the wind velocity, the "fetch" of the wind, i. e., the distance, windward, to the shore, and the size of the wave. The wave in turn sets the water beneath in motion, each particle moving in an elliptical path, whose minor axis, depth, is a function of the wave height. An excellent analysis of the relation between wind velocities, "fetch" and wave height is given by Gaillard (1).

(1) Professional Paper, Engineer Corps, U. S. A., No. 31. Wave Action. D. D. Gaillard, 1904.



Through the relation between wind action and height of wave, and the secondary relation between height of wave and depth of the movement of the water, it would appear that the velocity of wind would bear some definite relation to the depth of stirring. This relation is not one that can be deduced upon any of the present theories of wave action. In all such theories the principal of "continuity" is a primary assumption. That is, any given plane in the body of water at rest may, owing to wave action, become distorted but must remain continuous and unbroken. This mathematical conception is of course impossible of actual realization and the departure from the ideal condition is in fact the measure of the mixing of the water with which we now have to deal.

The relation between wind velocities and depth of mixing has been recently demonstrated in an ingenious and thorough manner by M. F. Sanborn.* The opportunity for such a study was rather unique. The Charles River Basin had been made by the construction of a dam by which the water within was maintained always at nearly high water mark. A lock in constant service, admitted
54 enough sea water to prevent the complete freshening of the

* Distribution of Sea Water in the Charles River Basin, after Excluding Tidal Water, M. F. Sanborn, Eng. News, 63, 272.

(Here follows diagram 7, marked page 53, Complainants' Exhibit 136.)

Exhibit 136-p. 53

basin and a permanent condition of stratification with regularly increasing salinity with increasing depth has resulted. Disturbances due to wind were therefore easily and quickly recognized by a study of the salinity after wind storms. The condition of uniform mixing thus brought about speedily gave way to the stratified condition normal to the basin and conditions were ready for another test. Sanborn tested the results, all told, of twenty-one storms, ranging in wind velocities from five to thirty miles per hour. The direction of wind was in every case up or down stream with a fetch of one or two miles. The accompanying plot (Diagram 7), is from Sanborn's paper. Stevenson (1) shows that the wave height and consequently the depth of the movement is proportional to the square root of the fetch, so that we may assume that depths approximately twice as great as those found in the Boston experiments will be disturbed by wind storms of corresponding velocities, in New York Harbor. The following values therefore represent the best of our present knowledge and are probably not far from the truth. Since the total effect of wind will be shown to amount only to a minor correction to our figures, approximate values in this case are all that is required. They are for average conditions over the Bay and are excessive for the rivers except during wind storms blowing directly up or down stream.

TABLE 15.

Effect of Wind Producing Vertical Mixing in Water of New York Harbor.

From results of Sanborn upon Charles River (Boston), corrected by observations of Stevenson upon relation of fetch and wave height:

Wind velocity. miles per hour.	Depth of uniform mixing, feet.
5	10
10	31
15	42
20	48

A study of the statistics of the United States Weather Bureau, has shown that during the four summer months, June to September, inclusive, the frequency of wind storms of varying intensities are as follows:

(1) Quoted by Gaillard, p. 67.

TABLE 16.

Frequency of Wind Storms of Stated Velocities.

(Compiled from Weather Bureau Chart.)

Wind velocity, miles per hour.	Average frequency (hours), June to September.
5	2.7
10	8.7
15	32.6
20	240.6

55 Combining these figures with those of Table 15, the frequency with which the water is disturbed to any given depth is determined. These depths and frequencies have been plotted, a smooth curve drawn through the points, and the following values reduced from the curve.

TABLE 17.

Frequency With Which the Waters of New York Harbor Are Uniformly Mixed to Stated Depth by Wind Action.

Depth of mixing (feet).	Frequency (hours), June to September.
12	2.8
20	3.0
30	8.0.
40	24.0

Discussion of the effect of this mixing by wind action will be postponed until the added effect of some other causes have been investigated. The slight breezes which always ruffle the surface have no material effect upon the result. They keep the surface and a few inches below in a state of constant admixture. The result is virtually to decrease the total depth by this amount. Reference to the figures in Table 13 will show that in depths of 20 feet or over a change of one foot in depth has but slight effect upon the rate of absorption.

Effect of Passing Vessels.

The currents produced by the movement of vessels are necessarily considered in a discussion of this kind. Vessels are commonly believed to exert considerable effect upon the aeration of the water. To determine this matter quantitatively the following procedure was adopted. If at any moment of observation, the total number of vessels in motion in the harbor is known, together with their respective speeds, drafts and breadth of beam (at water line), then the area

disturbed per unit of time will be the sum of the products of the respective speeds and beams expressed in common units. For example, a vessel having a beam of 40 feet moving at a speed of ten miles per hour, will disturb a water area of 35,000 square feet per minute. The total area of water being disturbed in this way at any unit of time has been determined by averaging the results of a careful observation and classification of the vessels to be seen at any one time in the Hudson and East Rivers, between the Lackawanna Station, Hoboken, the Navy Yard, and Governor's Island. These observations were made at various hours during the day for a period of two weeks. The most used waters were purposely selected for these determinations in order that maximum value might be obtained. For the same reason the hours of heaviest traffic only were taken and no attempt was made to get night observations. The results of the inspection and the average speeds and dimensions are given in Table 18. In this case as in the case of wave action the sum total of the effect is found to be of minor value, so that approximate accuracy only is required.

56 TABLE 18.

Statistics of Vessels.

Hudson River and East River Between Lackawanna Station, Navy Yard and Governor's Island.

Average of Daily Observations at Various Hours for Two Weeks.

Type of vessel.	Visible at one time.	Speed miles.	Beam feet.	Draft feet.	Area disturbed per minute. Square feet.
Ferries	7.5	14	40	12	369,000
Tugs	16.9	10	22	12	327,000
Tugs and Tow	6.6	7	100	12	407,000
Ocean Steamers	0.23	14	70	24	20,000
Schooners	0.39	7	30	14	7,000
Total					1,130,000

The total area disturbed calculated as described was found to be 1,130,000 square feet per minute. The total area of waters under observation is approximately 108,000,000 square feet. The proportion disturbed per minute is therefore 1/105 and the average time elapsing between successive disturbance of the same point is the reciprocal of this, or 105 minutes. The average draft is twelve feet so that it may be said that once in 1.75 hours any particular portion of the water of the Hudson or East River is stirred to a depth of 12 feet. Assuming such stirring to represent complete mixing, the data is now in form for reference to our absorption table. The effect of vessels amounts to but a few per cent of the total effect due to all disturbances.

Effect of Tidal Currents.

The third important agency in the mixing of waters like those of New York Harbor is one which is least noticeable in its action and which is consequently overlooked in general discussions of this subject. This is the vertical circulation due to tidal action. Tidal currents act in at least two distinct ways. There is first the effect of the velocity of the moving stream in passing through a changing cross-sectional area and second the effect of under-run produced at the meeting of fresh and salt water.

When any body of water moves through a cross section which is changing in area or direction local differences in pressure arise which cause vertical and horizontal circulation. To a minor extent, movement in uniform sections, is, owing to bottom resistance, a process of rolling rather than one of strict translation. This effect is aggravated by rough bottoms and by high velocities. In extreme cases "rips" result even where there are considerable depths. Less vigorous action leads to "boils," common upon rivers with irregular sandy bottoms, or in the vicinity of bends.

57 Mixing due to these causes is always quite complete throughout the depth, and owing to the large volumes which pass during a tidal cycle, this agency, where it is active at all, is of importance in the aeration of tidal waters.

In New York Harbor the waters which flow into the East River from the Upper Bay, either through the Buttermilk Channel or around the west side of Governors Island, are visibly subject to this action. At Hell Gate also there is complete vertical mixing of all the water passing. It happens that the volume of water in the East River between Hell Gate and the Battery is approximately equal to that which enters from each end during a half tidal period of six lunar hours, so that the average time between mixing of the waters of this river is about six hours. Some slight additional advantage is also derived from the relatively narrow cross-section and consequent pressure gradients across the current at maximum flow, from the bends and from the influence of Blackwell's Island. These all produce minor partial mixings through the vertical plane so that for these waters an average mixing period of five hours is probably conservative, and will be assumed.

The waters of the Hudson are less subject to action of the kind here described. Its width precludes any material cross-stream pressure gradients due to velocity of flow and side resistance and its uniform depth is not favorable to "boils." A portion of its flow is subject to overturning at Governors Island, but the amount is inconsiderable. The second class of tidal effect mentioned, however, is predominant in the Hudson, namely the effect of under-run. A careful study throughout the tidal cycle, as given by the U. S. Coast and Geodetic Survey (1) shows that at least once during each flood tide there is a fairly complete commingling of the waters throughout

(1) U. S. Coast & Geodetic Survey, Rep. for 1887, Append. No. 15.

the depth of the stream. This effect is confined to those waters in

which there is distinct stratification and is probably immaterial below Spuyten Duyvil, as indicated in the salinity table published by the Metropolitan Sewerage Commission. (2)

Above Spuyten Duyvil, therefore, an average time between mixings of twelve hours may be safely assumed.

That portion of the tidal prism of the bay and tributaries which passes through the Narrows may similarly be assumed to receive a thorough mixing at that point, but as this incoming water will be composed largely of pure sea water, with an oxygen content approaching saturation the advantage in this case is slight.

In the main body of the Upper Bay and Lower Hudson the mixing from tidal effect is slight at best and cannot be estimated even roughly. The effect of tides rising and falling upon sloping shores, of waves breaking upon those shores, and of minor irregularities in current leading to eddies and boils is at least small in comparison with the effect of Hell Gate for example, and the small additional aeration given to waters passing the latter point serves excellently to indicate the infinitesimal results due to these minor causes.

58 Summary and Conclusion.

These various results may now be summarized and added, as indicated in Table 19. It should be noted in particular that the effect of boats is the maximum effect found in the river and is largely excessive for the upper bay. Similarly the wind action is probably excessive for the Hudson and certainly largely so for the East River. The values are also all excessive in that fresh water coefficients of absorption only were available. It has been purposely intended to give results which shall be maximum values in every case.

TABLE 19.

Average Rate of Absorption of Atmospheric Oxygen in Various Parts of New York Harbor and Tributary Waters When 70 per Cent. Saturated.

Body of water.	Average time between mixing (hours).				Rate of absorption. Pounds per million gallons, per hour.

Depth of 20 feet	3.0	....	5	1.9	0.049
Depth of 30 feet	8.0	....	5	2.3	0.051

(2) Rep. Met. Sew. Comm. of New York, 1910, p. 529, Table IX.

The last column of Table 19 is obtained in the following manner: The upper twelve feet in the bay is completely mixed in the summer time on the average of once in 1.1 hours. Obviously the maximum effect of such mixing would result from a uniform distribution of the mixing periods. In assuming such a distribution therefore, which is the only possible assumption in a general analysis of this kind, the results will show a degree of aeration somewhat in excess of the truth. Similarly we may allow an average period of mixing of 8 hours for the 30-foot, and 24 hours for the 40-foot depths. Referring now to Diagram 6, it is seen that the average rate of absorption in 12-foot depths by water 70 per cent. saturated, during a period of 1.1 hours is approximately .045, and in 20-foot depths during a period of three hours 0.018 pounds per hour per million gallons of water. The values for greater depths have not been plotted, but at 30 feet during an 8-hour period the value is found to be 0.01, and at 40 feet during 24 hours approximately 0.005 pounds per million gallons.

59 In 20-foot depths one million gallons will therefore absorb altogether 0.018 pounds per hour plus the amount absorbed by twelve-twentieths of one million gallons in the upper twelve feet, or 0.027, making a total of 0.045 pounds. Similarly in 30 feet there will be an absorption per million gallons of 0.01 pounds, plus two-thirds of 0.045 pound, a total of 0.040 pound, and in 40 feet, 0.005 pound plus three-fourths of 0.040 pound, a total of 0.035 pound.

In the Hudson River above Spuyten Duyvil, a mean depth of 20 feet is assumed which an average mixing interval of 2.4 hours gives a rate of absorption of 0.019 pound per million gallons. The treatment of the East River is the same as that outlined above.

In each case the absorption in deep layers is determined as defined by their degree of quiescence, and to this absorption by the upper layers due to their more frequent periods of mixing is added.

It is of interest to note that the action of the wind and tide reverses the conditions found in quiescent water, in that the rate of absorption of oxygen per million gallons of water increases slightly with increasing depth down to about 30 feet. With the added action of boats this effect is not so noticeable, and in the final results the combined effect results in a very even rate of absorption so that special treatment of the 12-foot depths need no longer be considered and for all practical purposes the average rate of absorption in the bay and lower Hudson may be taken at 0.045, in the East River at 0.050, and in the upper Hudson at 0.019 pound per hour per million gallons of water in all depths less than 40 feet. The effect of aeration in depths greater than 40 feet may safely be disregarded.

There remains only the discussion of minor tributaries. Of these the Harlem is of the greatest interest. This rapid flowing stream is undoubtedly more thoroughly mixed throughout its course and throughout most of the tidal cycle, than any other body of water dealt with here. The relatively small volume of water passing through the Harlem makes it of minor consequence. Of the other bodies of water tributary to the Bay there is none that is as favorably affected either by wind or tide or vessels as are the Hudson and

East Rivers. There are doubtless many small bays that have shallower depths, but reference to diagram 6, plate 16, will show that even in depths of ten feet, with periods of mixing of twelve hours or more the rate of aeration is not greater than those that have been found in the bay.

60

Chapter III.

Investigations Upon the Aeration of Sewage.

General.

The purification of sewage by biological means may be carried out to any degree of perfection desired and at costs that vary with the efficiency of the process. The most economical of such processes, and the least efficient, as measured by the degree of oxidation resulting, aims at producing complete stability in the organic matter. The effluent from a trickling filter for example, if discharged into a stream, will cause little or no reduction in the dissolved oxygen and natural purifying power of such stream.

Between this condition of practically complete stability and the condition of crude sewage, which is highly decomposable, lies a great range of possible conditions of partial oxidation which may be denoted numerically as lying between the limits of zero and 90 per cent. relative stability upon a scale in which complete stability would be represented by 100 per cent. In studies of sewage disposal by dilution this relative stability factor is one of prime importance since it measures directly the resulting effect upon the waters in question. Hitherto, little if any attention has been given to the problem of producing effluents having stabilities within the range indicated.

The experiments here reported were undertaken to determine if by some suitably arranged plan of artificial aeration, such partial purification could be accomplished at reasonable cost. Since biological filters are but mechanical devices for bringing together in close contact the three elements which enter into the oxidizing reactions, namely sewage, oxygen and bacteria, it was hoped that by increasing the ratio of sewage to oxygen volumes within a given tank space, and thus reducing the space required for purification, partial oxidation would result which would be of value under the peculiar local condition. These experiments were divided into three series. Series I. included investigation in shallow tanks upon both crude and septic sewage. Series II., investigations in a deep tank with septic sewage alone, and Series III., investigations, with a modified septic tank known as a biolytic tank. The first two series were made at Brooklyn and the last at Boston.

Series I.—Aeration of Crude and Septic Sewage in Shallow Tanks.

Plan of Investigation.

The purpose of these experiments was to determine, first, whether the stability of raw or septicised sewage could be increased by forced aeration, and, secondly, under what conditions, with what volumes of air and at what cost the maximum economic efficiency of such a process could be attained. For this purpose arrangements were made at the sewage disposal works located in East New York for pumping directly from the outfall sewer a continuous flow of sewage sufficient for these investigations. This sewage was first pumped to an elevated supply tank from which it flowed by independent lines to a septic tank and to an aerating tank. The sewage from the septic tank overflowed to a second aerating tank; we were thus en-
61 abled to aerate both the crude sewage and the septic sewage.

During a portion of this period of investigation aeration of the septic tank effluent was accomplished by pumping compressed air to the bottom of the tank through six parallel lines of pipe, each furnished with a row of ⅛-inch holes along its top line. For the purpose of better distribution of this air a fine mesh copper gauze was soldered around the air pipe so that the space between the pipe itself and this guaze became virtually an air chamber. During the second period of the investigation in addition to the arrangement just described, the tank was provided with frames upon which common laths were nailed in such a way that vertically and horizontally these laths were about one inch apart and at an angle of 45 degrees. The rows of laths were also staggered both verticallly and horizontally. This arrangement gave throughout the body of the tank a very large surface for the development of bacterial growths upon which we relied for improved efficiency and it also served to improve the distribution and delay the passage of the air as it flowed upward. The aerating tank used with the crude sewage was constructed in exactly this same way at the beginning. The total capacity of the septic tank was 3,200 gallons; of the septic aerating tank 1,495 gallons; and of the raw sewage aerating tank 740 gallons. The average rate of flow through the raw sewage tank was maintained throughout at 13,000 gallons per day, making the period of treatment 1.4 hours. The septic tank and aerating tank were first operated at the rate of 13,000 gallons per day, making the period of septic action 5.9 hours and of aeration 2.8 hours. Later the capacity of the septic tank was decreased one-half as was also the rate of flow, thus maintaining the rate of septic treatment at the same figure but increasing the time of aeration to 5.6 hours. Considerable difficulty has been experienced in maintaining a steady flow of air through these two tanks and in particular in apportioning that flow in the desired ratio. It is believed, however, that the average conditions of air flow and the average results obtained are fairly representative.

Chemical Methods.

Chemical analyses have been made of the raw sewage before and after aeration and of the septic sewage after aeration. In changes in the character of the sewage with reference to its stability or its oxidizability, the ordinary methods of chemical analysis do not indicate the significant factors. One factor of importance is the dissolved oxygen contained in the liquid in question. Of chief importance, however, is that factor which we call the stability of the sewage which is the reciprocal of its tendency to withdraw oxygen from a stream. This stability factor we have estimated in two different ways. The first is known as the relative stability method or more commonly the putrescibility. In this method the liquid is mixed with the different proportions of water containing a known amount of dissolved oxygen. A sensitive indicating dye known as methylene blue is added to the mixture and the whole is preserved in a stoppered bottle and kept under constant observation. This blue dye has the property of losing its color when the dissolved oxygen of the liquid has entirely disappeared. The time required to so decolorize a sample is a somewhat complicated logarithmic function of the stability. This function has been determined as the result of an extended series of investigations upon all classes of sewages
62 and effluents so that we now have a well-defined relation between the time required for decolorization and the so-called relative stability. This relative stability is the ratio between the amount of oxygen available in the diluted sample and the total amount of oxygen which would be utilized by that sample in its complete oxidation. Thus a sample of such a mixture which had a relative stability of 50 per cent. would contain just half the amount of oxygen which would be required to render it perfectly stable. This method is easy of application and is the one most commonly employed in sewage work. A more delicate method for obtaining the same information, and one which was devised for this work and used here for the first time is the following:

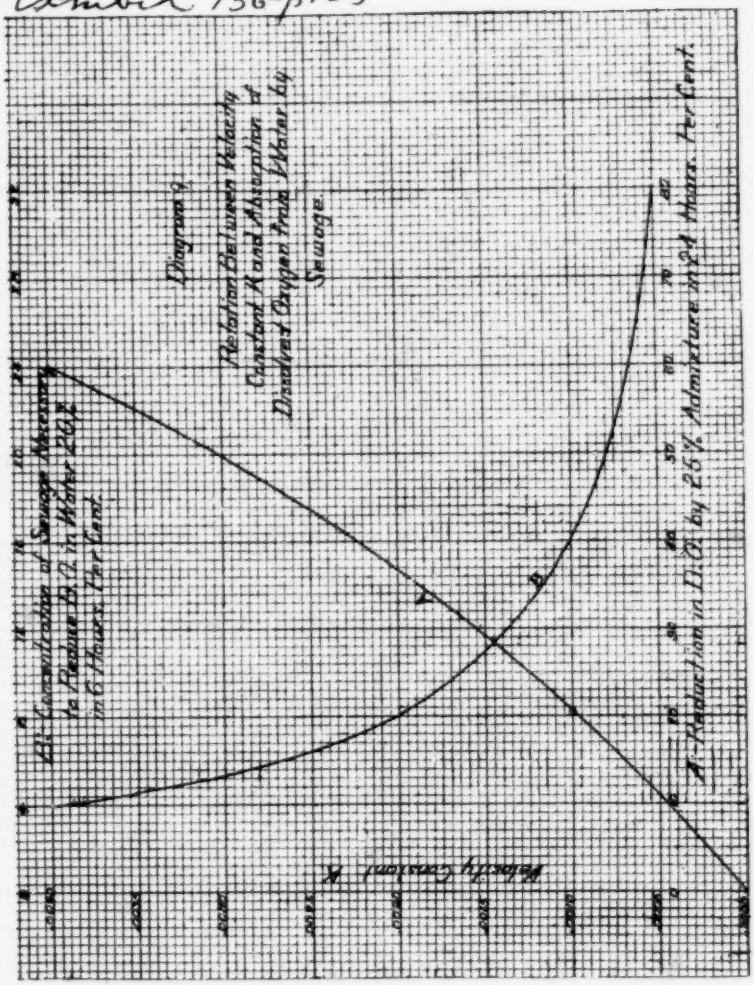
Suitable mixtures of the sewage in question with oxygen-saturated water are made and the total amount of oxygen in the mixture determined immediately. The sample is then stored in a tight bottle for a suitable period of time and a redetermination of the amount of dissolved oxygen present is made. The rate at which the oxygen disappears under these conditions gives us an index of the oxidizability of the organic matter and a more direct measure of the probable effect upon the stream than is given in the methylene blue method. The theoretical basis for this method will therefore be discussed in some detail.

Considering the reaction taking place between the organic matter of the sewage and the oxygen dissolved in the water the following relation should hold

$$\frac{dO}{dt} = K\,O\,C$$

In which O is the amount of oxygen present in unit volume, C the amount of organic matter oxidizable, t the time allowed for the reaction to proceed, and K a constant determined by the character of the organic matter and in turn defining the oxidizability of that organic matter. Integrating

$$\log \frac{O'}{O} = K\,C\,t$$



O′ being the initial and O the final amount of oxygen present.

The constant K defines mathematicallly the rapidity with which the oxygen is used in a mixture of water and sewage. It depends upon the character of the sewage matter and the concentration of that material in the sewage and is independent of the extent of dilution or character of diluting water. A value of K = .0030 would indicate a sewage which in 25 per cent admixture with water would reduce the oxygen content of the mixture 50 per cent. in four hours. Similarly for K = .0020 the reduction in a 25 per cent. admixture in four hours would be 37.5 per cent. and with K = .0015, 28.5 per cent. These figures are tabulated in column A below to serve as a standard for interpreting the results of our experimental work.

In column B a set of figures are given which show the percentage of sewage of given K value which could be discharged into a stream under the condition that the oxygen of that stream shall not be reduced more than 20 per cent. in six hours.

(Here follows diagram 9, marked page 63, Complainants' Exhibit 136.)

Exhibit 136-p. 63

64

K	A	B
.0030	50.0%	5%
.0020	37.5%	8%
.0015	28.5%	11%
.0010	20.0%	16%

A—Reduction in dissolved oxygen which would result at the end of four hours in a 25 per cent. admixture of sewage in water.

B—Maximum concentration of sewage permissible if the oxygen shall not be reduced more than 20 per cent. in approximately a half tidal period of six hours.

The relationship is shown more fully in Diagram 9.

Results Obtained.

Chemical Analyses.—Samples were collected daily throughout most of the period covered by the work. During the latter part of the period they were collected every other day. Composite samples, preserved with chloroform, were analyzed weekly. The results are given in Table 20 in the form of monthly averages. For comparison an average analysis of Boston sewage is given.

* Second series of experiments begun.

The high nitrogen values indicate a sewage much stronger than the average and possibly containing nitrogenous manufacturing wastes, such as brewery waste. The low suspended solids on the other hand indicate a considerable deposit in the outfall sewer. Considering the strength of this sewage its stability is high. The sewage of Boston is fully as putrescible as this sewage, measured in terms of oxygen absorption from water, but in chemical composition it is much weaker. This bears out the indication of some relatively stable manufacturing waste. It would appear that we are dealing with a sewage which, although strong according to our analytical results, is not more decomposable than an average city sewage. Improvement by aeration would, therefore, be relatively more difficult.

The analyses of the crude sewage after aeration and of the same sewage after having passed the septic tank and the aeration tank are also given in Table 20. No changes are noted other than those which can be ascribed to the action of the tanks themselves.

Relative Stability.—The relative stability results as determined by the methylene blue test are given in Table 21.

Period 5—May 13 to June 26.
Period 6—June 27 to August 19.
Baffle screens used during Periods 1, 2, 5 and 6.

The raw sewage shows a constantly decreasing stability as is always the case during this season of the year. Direct aeration at the rate of .20 cubic feet of air per gallon of sewage increases the stability by about 45 per cent. in a 25 per cent. mixture, and 53 per cent. in a 30 per cent. mixture. During the second period the rate of application of air was decreased to 09. and the increased stability for this period in a 25 per cent. mixture was 72 per cent. It is possible that still less quantities of air would give results approximately as good, but upon the basis of this work it is evident that no greater quantities than 90,000 cubic feet per million gallons will be required.

The septic sewage results must be considered in four separate periods. During period "3" the rate of application was .36 cubic feet per gallon, and the increased stability over the raw sewage for the corresponding period was 32 per cent. in a 25 per cent. mixture; during the fourth period the time of contact with the air increased from 2.8 to 5.6 hours, the other conditions remaining the same except that now the rate of application of air was .67 cubic feet per gallon. The stability in 25 per cent. mixture was increased only 13 per cent. During the fifth period screens were installed similar to those already in use with the crude sewage, the rate of application and time of contact remaining the same, which resulted in an increased stability of 62 per cent., calculated on the crude sewage for

this period. During the sixth period the air was diminished
67 to 0.23 cubic feet per gallon, and the time of contact to 2.8 hours, with a resulting improvement in stability at 25 per cent. dilution of 89 per cent., the highest value recorded during these studies. A part of this improvement is doubtless due to the decreased stability of the sewage itself already noted, and the same statement may be made in regard to the second period of the raw sewage experiment, in which decreasing the amount of applied air did not materially affect the result. The results of these last periods are approaching summer conditions and it is doubtless true that with the coming of warm weather and the consequent lessened stability of the crude sewage, high percentages of improvement are more readily obtained. As it is summer conditions that really limit any dilution process of sewage disposal, these warm weather results have the greatest significance in this present study.

Putrescibility Coefficient.—The results obtained by the putrescibility coefficient are, when suitably interpreted, the most satisfactory basis for determining the results of the work of this character. In Curve B, Diagram 9, the maximum permissible concentration of sewage in a body of water is given for all values of the coefficient, under the condition that the dissolved oxygen shall not be reduced by more than 20 per cent. in six hours. For purposes of comparison any other value might have been selected. Measured by this practical test the percentage improvements in the sewage under treatment as shown by the data of Table 21 were as follows:

TABLE 22.

Percentage Improvement in Condition of Sewage Brought About by Aeration, as Measured by Concentration of Sewage Required to Reduce the Oxygen Content of Water 20 per Cent. in Six Hours.

Summary.

Full discussion of these results will be reserved for a later place.

Series II.—Aeration of Septic Sewage in a Deep Tank.

Our investigations up to this time had shown that a satisfactory partial oxidation of crude sewage could be accomplished under the conditions prevailing in the experiments. The volume of air required relative to the sewage flow was considerable, however, and the cost of such treatment seemed unnecessarily high. Examinations of the air leaving the aeration tank showed conclusively that the oxygen content was far from being exhausted. In fact, the air was

practically of normal composition upon leaving the tank as far as we could learn from chemical analysis. In other words, the actual amount of oxygen absorbed from this considerable volume of air was infinitesimal. It seemed therefore that the same body of air might to good advantage be used to treat a larger volume of
68 sewage at a consequent decreased cost of pumping. This result could only be obtained by increasing the depth of the tank. In two tanks of unequal depth through each of which sewage is flowing at a stated velocity and into each of which a stated volume of air is passing, the sewage in that tank having the greater depth will obviously receive exactly the same treatment as that in the smaller tank, but the relation of air volume to sewage will be inversely as the depths.

Plan of Investigation.

To test the efficiency of this procedure, a tank twenty-one feet in depth to the water line was built out of two-foot lengths of 24-inch vitrified sewer pipe set up in a vertical stack. Through the central axis of this stack a three-quarter-inch iron pipe passed from top to bottom and upon this pipe circular discs of No. 12 expanded metal lathing were placed at one-foot vertical intervals. Sewage was admitted to this stack through a two-inch pipe at the bottom, this pipe coming from the overflow in the septic tank used in our previous experiments. The sewage overflowed from a pipe at the top of the stack. Compressed air was pumped through the three-quarter-inch iron pipe mentioned and was distributed at the bottom of the stack through one-eighth-inch holes spaced two inches on centers upon four cross arms 90 degrees apart, extending from the center to a point near the periphery. Compressed air was supplied by the compressor used in the previous experiments. The capacity of the air compressor was determined under the working conditions by inserting a pressure air meter in the line and calibrating the pump by revolutions. Subsequently the rate was controlled by pumping as nearly as possible at a fixed number of revolutions and wasting the desired amount through a by-pass which was metered. The actual amount of air used was then taken as the difference between the original pump rate at the given speed and the amount of air measured in the waste line. The experimental portion of this work was divided into two periods:

During the first, a four-hour period of septic treatment and a one-hour period of aeration were allowed. The rate of flow of sewage through the tank during this period was 486 gallons per hour and of air about 110 cubic feet, so that air was being applied at the rate of approximately 0.23 cubic feet per gallon.

During the second period, the rate of flow throughout the system was reduced one-half, so that the time of septic treatment was made eight hours and of aeration two hours. The volume of air was decreased proportionately, so that the net effect of this change was to increase the time of treatment only.

Results Obtained.

These experiments were controlled by the same chemical tests as were made in the first series. They extended from September 10 to September 23, in the first period, and from September 23 to October 6 in the second period. As the sole purpose of this series of experiments was to determine whether results comparable with those obtained in Series I. could be obtained in the deeper tank at a correspondingly less volume of air relative to sewage, it was not continued longer than was necessary to demonstrate the facts. The average results of each period as measured by the two methods already described are summarized below.

TABLE 23.

Relative Stability, Dissolved Oxygen and Putrescibility Results and Other Data.

Series II.

Sewage.	Period.	Air, cubic feet per gallon.	Time of contact, hours.	Reltive stability, dilution per cent.					Putrescibility coefficient K, dilution per cent.		Dissolved oxygen.
				20.	25.	30.	35.	40.	5.	15.	
Crude	1	....	..	78	60	49	..	..	.0054	.0058	2.0
Aerated septic	1	0.23	1	..	..	94	85	77	.0011	.0015	6.2
Crude	2	....	..	80	68	52	..	..	.0069	.0080	.80
Aerated septic	2	0.23	2	..	..	77	62	44	.0028	.0044	4.4

70 In interpreting these results it is necessary to bear in mind the fact already developed early in these investigations —that the putrescibility of the sewage itself changes greatly from season to season, largely owing to temperature changes. Therefore the ratio of improved stability obtained in this series of experiments is the point of particular significance. No direct comparison of actual K values or of stabilities as determined by the methylene blue test can be made between these results and those of the first series, which were made during the warmer summer months.

The improved stability as measured by the methylene blue test at 20 per cent. is 93 per cent. in period one (1) and 48 per cent. in period two (2), and as measured by the putrescibility coefficient 380 per cent. and 145 per cent., respectively.

On the whole, it is seen that the relative improvement is decidedly greater than was observed in Series I. It is not certain that results of maximum efficiency are obtained in this case, owing to the comparatively small amount of air necessary; the compressor in use could not be controlled at any lower rates, but the evidence indicates that satisfactory results could be obtained with relative air volumes somewhat less than those actually used.

Analyses of the air escaping from the top of the tank were made on several occasions and showed that about 2 per cent. by volume of the total amount of air passed, or 10 per cent. by volume of the oxygen content of that air had been exhausted in its passage through the tank. It is therefore apparently only a matter of engineering economy in the construction of deep tanks which will determine the most economical depth to be employed. Obviously the economy of this treatment increases in direct proportion to the depths of the tank.

Series III.—Experiments Upon the Aeration of a Biolytic Effluent, at Boston, Mass.

The two series of investigations which have been reported thus far made use of a septic tank effluent which was at all times devoid of oxygen and was throughout a considerable period of this work exceedingly putrescible. It is a well-known fact in sewage chemistry that with increasing age of sewage there is a corresponding decrease in oxygen dissolved values and that this change does not end when the zero value is reached. Under the anaerobic conditions which then result, the sewage becomes exceedingly avid for oxygen so that an old septic effluent will oftentimes absorb almost immediately more oxygen than the original sewage would have absorbed in many hours. There is reason to believe that this increased avidity for oxygen is due in a large measure to easily oxidized gaseous or mineral compounds, so that oxygen used up in accomplishing such oxidation is largely wasted. On the other hand, it is quite possible that this increased avidity is a direct measure of the ease of oxidation of the entire mass of the organic matter, in which case these conditions are distinctly favorable. The results of the first series of investigations reported seemed to indicate that other things being equal a septic effluent would rapidly use up a larger amount of oxygen than

with a corresponding crude sewage with no additional beneficial results in the matter of stability than those which could be ascribed to the partial loss of suspended solids which is incidental to the septic process. It was thought best, therefore, to obtain more data upon the question of the desirability or otherwise of first septicizing the sewage before aeration.

71

Plan of Investigation.

At the Sewage Experiment Station of the Massachusetts Institute of Technology, a tank of somewhat novel design has been in operation under the direction of one of the writers for about eighteen months. This tank has been called a "biolytic" tank. It is essentially a deep rectangular tank with a hopper-shaped bottom. The sewage enters through a pipe down the center and is discharged at a point near the bottom of the tank. It flows upward in a column whose cross section is constantly increasing and whose velocity is consequently decreasing, overflowing at eight points about the periphery. The purpose of this tank and of this peculiar mode of operation is to prevent the accumulation of the products of decomposition in the bottom layers and to keep the sewage as fresh as possible consistent with satisfactory sedimentation. The tank effluent is well clarified and in much more satisfactory condition for treatment upon sand filters or other oxidizing mechanisms than is the effluent of the septic tank.

The aeration system was installed in the upper two feet of this tank, essentially similar to the arrangements used in the first series of these experiments. Our results thus far having indicated the possibility of increased economy with increased depth, the question of depth and relative volumes of air are not deemed of importance in these experiments. If satisfactory results could be obtained during a stated period of treatment such as one or two hours the economy in air compression which would result from the use of deeper installations could easily be determined. The installation, therefore, consisted of a series of seven horizontal air distributors essentially like those already described, above which was a system of inclined slats like those used at Brooklyn, two feet in depth. This tank had a cross-sectional area at the top of approximately 50 square feet. The rate of flow through the tank was eight thousand gallons in twenty-four hours, which gives an upward velocity in the upper section of 0.88 feet per hour. The time of exposure to the air was therefore approximately two and a quarter hours.

Results.

Results by the putrescibility coefficient only were obtained in this series. During the experiments putrescibility coefficients were obtained at a great many dilutions in order to determine thoroughly the significance of this test. The averages of all coefficients obtained during the period, October 1 to December 31, 1910, were

Crude sewage	.0022
Septic aerated	.0020

which by Diagram 1 gives an improvement of 10 per cent., as measured by the dilution of these sewages which will reduce 20 per cent. of the oxygen of the water in six hours.

This poor showing is evidently due to difficulty in getting aerobic conditions established in the tank which had been anaerobic
72 for over a year. During the months of November and December, when improvement was most difficult in Brooklyn, the average results of the Boston tests made at 5 per cent. dilutions were

Crude sewage	.0023
Septic aerated	.0012

The improvement here, measured as before by Diagram 9, is 92 per cent. These results show strongly the necessity for a separate aeration tank following the septic treatment. The two processes cannot be combined in one tank.

Conclusions.

Amount of Air Required and Improvement Effected.

The amount of oxygen necessary to give significant results has been determined regardless of cost or other considerations. In the case of the crude sewage it was found that a rate of application of 110 thousand cubic feet per million gallons gave an excess of dissolved oxygen in the sewage which indicated that no further advantage would be obtained by increasing the air supply. In the case of the septic sewage an equal rate of application gave no such evidence of excess and an effort was made to add the air at a sufficiently high rate to show some excess. This effort was only partially successful and in no case was the excessive oxygen in this effluent as great as in the raw sewage effluent. For this reason also the time of contact was doubled without any appreciable results in the excess of oxygen. It was soon discovered that it was useless to attempt to get any noticeable excess in this septic sewage and that even at the lower rates the stability of the septic sewage was increased and at the higher rates of application was fully equal to that of the aerated crude sewage. Analysis of the air leaving the liquid also showed that the absorption of oxygen from this air was very little indeed so that it seemed desirable to decrease rather than to further increase the amount. The result obtained during period 6 amply justified this conclusion. These results are so far superior to those obtained with crude sewage, that there is every indication that highly satisfactory results could have been obatined at still lower rates of treatment.

Imperfect distributing apparatus made it impossible to further reduce this rate and study this matter further in the limited time that was available. The results of Series II. are of especial interest in indicating still further economy in air. The much greater effi-

ciency obtained during the first period of treatment indicates a distinct advantage in favor of shorter period of septic treatment. Again it was found impossible with the large capacity of the air compressing machinery and meters to reduce the air flow to what was strongly indicated as the point of maximum economy.

The Boston experiments were not planned to determine possible economy in air since only a shallow depth was available, but the result of all this work taken together enabled conclusions to be drawn that were not indicated in any single series. Period 6 of Series I, gave the best results in a shallow tank with an air consumption of 0.23 cubic feet per gallon and a contact period of 2.8 hours. Series II, shows that economy in air and tank space, and efficiency increase with the depth, other conditions being equal. Together with Series III, it indicates a great advantage in short septic periods. All the data taken together plainly show that, during the hot weather months, the critical period in harbor conditions, the stability of a sewage as measured by its withdrawal of oxygen from the diluting waters, can be increased from two to three fold by the application of short period septic action, and by aerating in a deep tank; and that an air consumption of approximately 0.1 cubic feet per gallon will doubtless be sufficient under these conditions. This means that under any stated conditions of permissible pollution in the harbor waters the maximum amount of sewage which can be disposed of in the harbor is increased two to three fold by this treatment.

73

Sludge.

The question of sludge disposal is one which is common in all sewage treatment and has not been investigated here. The Biolytic tank in use at Boston is designed with special reference to this problem. Its function is to reduce the sludge problem to a minimum by providing for maximum liquifaction in the tank. Results of the operation of the tank will soon be published in another place. It can be stated that the sludge problem will at least be not greater than in other processes and can by proper design of tanks be very much reduced if desirable. The amount of finely divided suspended matter which the tank will discharge is controlled by the design. The amount which should be discharged under any given local conditions can only be determined by local studies. It will be found advantageous to discharge a maximum quantity as determined by stream flow and dilution in any case. The remainder will have to be dealt with by methods now in vogue, most likely by removal in scows.

Cost of Aeration.

The relative costs of low pressure air compression by means of compression and rotary blowers has not been gone into in detail. There would seem to be some advantage in the use of deep tanks and higher pressures, up to possibly thirty feet. On the other hand for lower pressures, up to five or six feet, the blower type of air pump is highly efficient.

A blower of this type having a capacity of fifty thousand cubic feet of air per hour under a five-foot head of water requires about 25 K. W. of current, net.

At the rates of aeration which we have finally adopted, this blower would care for a sewage flow of half a million gallons per hour. At a cost of 4 cents per K. W. hour these costs for current alone would be two dollars ($2) per million gallons. This refers to small electrically operated plants at sewer outfalls. For larger installations, the cost of power would not exceed one-half this amount. We estimate the total cost of installation of plant in the neighborhood of two thousand dollars ($2,000) per million gallons daily capacity, or about one twenty-fifth the cost of sprinkling filters after deducting land costs. Labor charges should be exceedingly low.

It should further be noted that under conditions in which such a process might be necessary and sufficient, the necessity for
74 its use would arise only during the summer season, of perhaps four months each year. If winter conditions demand treatment at all then the summer conditions would not be met by aeration, since the variations we have noted between summer and winter sewages are greater than the improvements obtained.

Under certain local conditions also less perfect results than have been obtained here might be ample. The merits and possibilities of this process have only been barely indicated in this investigation and a fruitful field has been opened up for future investigation.

75

Chapter IV.

Studies for Sewage Disposal from Certain Districts.

Flushing Drainage District.*—This district is bounded on the south by the ridge near Hillside road, which forms the divide of the watershed to north and south; on the west by Flushing Bay and the high land west of Flushing Creek; on the north by the Sound and on the east by Little Neck Bay and the low lands extending from the head of that bay to the ridge first mentioned. The total area is 14,923 acres, and the estimated future population on a basis of 50 persons per acre for the towns and 25 persons per acre for suburban districts, is 423,425. For the purpose of determining possible points of discharge a trunk sewer system had to be designed, on the separate system for the unsewered parts and with storm water overflows where the combined system is now installed. This system as designed serves all of the district and is adequate to the needs of the estimated future population. A water consumption of 125 gallons per capita per day was assumed and an allowance of .003 cubic feet per second per acre was made for ground water flow, based on the practice of the Borough Engineer of Brooklyn. Further assumptions made were as follows: that of the total

* See map showing Drainage Districts of Jamaica, Corona, Flushing and Westchester following p. 148. The writers are indebted to Mr. E. F. Robinson for valuable assistance in the Drainage District Studies.

flow per 24 hours, half would pass in eight hours; that the maximum velocity with sewer 0.8 full should not exceed 7.5 feet per second; and that the minimum velocity with sewer 0.2 full should not be less than 1.50 feet per second.

It was found that the drainage from the entire area could be brought to a point in the East River east of Powells Cove and then discharged, and that five-sevenths of the area could be drained by a high level gravity system to the point of discharge, with a low level gravity system for the remainder, discharging into the high level system by pumping. Possible sites for purification works were found should such prove necessary. Details of the recommendations made are given in the special report rendered March 20, 1910.

Corona Drainage District.*—This district comprises the territory between the Flushing District on the east, the dividing ridge on the south, the Borough of Brooklyn and Newtown Creek on the west and the East River on the north. Its area is 14,535 acres and the estimated future population on the basis described for the Flushing District is 628,200. This includes an area of 756 acres with an estimated future population of 37,800 for which the natural drainage is through the sewers of Brooklyn. Another portion containing 1,290 acres with an estimated future population of 64,500 along the water front from Astoria south and west to Newtown Creek and lying below the 20-foot contour, is now drained into Newtown Creek and the East River. Eventually its sewers will have to be intercepted and discharged by pumping into the main system.

For the remainder of the district a gravity system of trunk sewers has been designed by which all of the sewage is carried to and discharged into deep water of the East River from a point approximately to the southeast of Berrians Island.

76 Should purification works become necessary, these can be located on Rikers Island, to which the system can be prolonged.

The sewers were designed on the same assumptions as those for the Flushing District. Provision for storm water overflows has been made at points where the proposed interceptors receive the discharge of existing combined systems, and at two points along Flushing Bay and one point near the head of Newtown Creek. While the sewers were designed for sanitary and ground water flow only, they are of capacity sufficient for the estimated future population and until the present population shall have increased greatly they can be utilized for storm water flow.

There is now a sewage purification plant at Elmhurst, which is capable of caring for the sewage of the district tributary to it for the present and if improved can be utilized for the increasing population for some years and thus render unnecessary the immediate construction of a portion of the projected system.

Full details of the system as projected are given in the special report dated May 24, 1910.

Jamaica Drainage District.*—This district comprises the areas draining naturally into Jamaica Bay as well as Coney Island, Rockaway Beach and a small area near the head of Little Neck Bay, within the limits of Greater New York, but cut off by a ridge from the Flushing District system. In general it is bounded on the north by the ridge which forms the southern limit of the Corona and Flushing Districts, on the east by Nassau County, on the south by Jamaica Bay and on the west by Gravesend Bay.

The estimates for future population were made as in the other districts. Inasmuch as it is expected that the portion of the district contiguous to Jamaica Bay, for which a population of 50 per acre has been assumed, will be developed chiefly for manufacturing and commercial purposes, a water consumption of 100 instead of 125 gallons per day has been allowed, which gives an equivalent population of 40 per acre with a water consumption of 125 gallons per day. In the cases of Coney Island and Rockaway Beach, the permanent population is small in comparison with the number of daily visitors throughout the summer months. For Coney Island a maximum population of 500,000, with an average daily water consumption of 15 gallons per capita, has been assumed, and it is further assumed that the total run-off will take place in 12 hours. These assumptions when reduced to terms corresponding to those used for other districts would give a permanent population of 70 per acre with a daily per capita water consumption of 125 gallons. Similar assumptions for the Rockaway section give an equivalent permanent population of 50 per acre, with a daily water consumption of 125 gallons. Other assumptions as to population, water consumption, ground water run-off and ratio of maximum to average discharge are the same as for the FlushingDistrict.

The total area in the Jamaica District is 48,916 acres. The total estimated future population is 1,661,495.

Jamaica Bay is a land-locked tidal basin of slight depth, in which the entire tidal prism is filled and emptied during each tidal period.

77 Partial purification of the sewage discharged into it will be required, but even with such purification, to secure an adequate degree of diffusion there must be several points of discharge. For the portion of the Jamaica Bay drainage area of the Borough of Queens, the system as projected gathers all of the sewage by gravity at two main concentration points, one at the present Twenty-sixth Ward Pumping Station, and one on Cornell Creek, from which it will be discharged through iron force mains into Fishkill and Broad Channels, respectively. When under the proposed project for improvement of Jamaica Bay, a thirty-foot channel has been formed along the north side of the Bay as far as these discharge mains, they must terminate in that channel, and it will then be essential to provide the most efficient means of diffusion practicable on discharge in order to avoid the formation of local nuisances. Storm

* See map showing Drainage Districts of Jamaica, Corona, Flushing and Westchester, following p. 148.

water overflows are provided whenever existing sewers of the combined system are intercepted.

The eastern section of the Borough of Brooklyn comprised in the Jamaica District already had approved plans for sewerage, and the project had to be formed with due regard to these plans. The project contemplates the collection of the sewage by gravity at three points where it is lifted to a higher level and conveyed by gravity to proposed purification works in Riches Point Meadow, and then lifted and discharged into Rockaway Inlet, the ebb currents from which pass seaward, without touching the bathing beaches of Coney Island or Rockaway Beach.

The western sections in the Borough of Brooklyn are already provided with approved projects partly carried out. In the complete project only a few additions were required.

Two distinct systems of disposal are practicable for the Coney Island sewage. One is to force the sewage north to the concentration point established for the sections to the north and thence to lead and discharge it into the Narrows, through the interceptor already constructed. The second is to discharge it to the south by pumping into the sea, not less than 2,000 feet from shore, and at a point from which currents do not lead to the beach. The latter plan is recommended, since the inadvisability of increasing the pollution of the harbor in any case where it can be avoided is manifest.

The Little Neck Bay section is of a limited area. It is proposed to concentrate the sewage from it at the head of Little Neck Bay and after purification to discharge it into the bay.

The Rockaway section is low and flat. It is proposed to collect the sewage from it at three points, and after coarse screening and sedimentation with liquefaction for a short period in hydrolytic tanks, to discharge it into the sea at least 1,000 feet from the shore line, from which there is no probability of its being brought back to any appreciable degree.

Disposal in Jamaica Bay.—As stated earlier, Jamaica Bay is a land-locked tidal basin, of which the tidal prism is filled and emptied during each tidal period through Rockaway Inlet. After passing the fanshaped bar between Rockaway Point and Coney Island, outside the outer extremity of the inlet, the inlet has a deep channel of ample width which extends as far east as Barren Island. There this main channel is divided into several minor channels. One follows the north shore of Rockaway Point, others pass northeast between the islands of the bay, and the most westerly follows generally the west shore of the bay. These channels are
78 formed and maintained by the tidal currents. But there is no current circulation between the heads of the channels along the north side of the bay other than such as may be produced temporarily by wind action. Excepting as moved by the winds, the waters on the north and east shores are quiescent. Under such conditions it is evidently necessary that the sewers be extended into the channels as in the project.

The total flow through Rockaway Inlet as determined by the observations of the Engineer Department, U. S. Army, is for flood 4,550,000,000 cubic feet. This is the measure of the tidal prism. From the map of the bay the portion of the tidal prism tributary to each channel was determined and from this the mean velocities of flow in the channels calculated. Assuming the sewage discharge through each of the outlets on the basis as calculated for the project and beginning with pure water in the bay, the amount of partially polluted water due to the discharge at the close of an ebb tide and remaining in the channel at the beginning of the flood period was determined and the ratio of sewage to pure water obtained. It is evident that this ratio is at first too large, since at first no previous pollution is assumed. By continuing the process the ratio grows smaller by decreasing decrements until the decrement practically vanishes and the ratio then represents the true proportions of the average admixture of sewage and sea water which result from the discharge of the assumed volume of sewage. While the dilution figure fairly represents an average condition, the pollution in the immediate vicinity of the sewer outlet will be much greater even with the best process for diffusion possible, and to avoid local nuisance, it will be necessary to have the dilution ratio large. We believe that this figure should not be lower than 1 part sewage to 117 parts sea water at 63 degrees Fahrenheit.

The sewage discharged into Rockaway Inlet from Riches Point Meadow, if considered alone, would have an ultimate dilution, determined as indicated, of one part in 2,670, but when considered together with the discharge into other portions of the bay the average ultimate dilution is 1 in 209. The discharge into Big Fishkill Channel will have an average ultimate dilution of 1 in 75. That discharged into Broad Channel will have an average ultimate dilution of 1 in 95. These figures are based upon an assumption of thorough diffusion. At periods of slack water the percentage of pollution will be much greater.

The dilution ratio of 1 in 117 was adopted as necessary in view of the volume of oxygen absorbed by sewage under summer conditions (1,950 pounds per million gallons in 12 hours), the available supply in the tidal basin, and the consideration that under the worst conditions this supply must never be reduced below 50 per cent. of the saturation value, which would make an average reduction to 75 per cent. of saturation value a standard with a small margin of safety.

Complete purification before discharge is evidently never necessary under the conditions prevailing in Jamaica Bay with sewage concentrated and discharged under the project outlined in this report. During the winter season even partial purification will probably be unnecessary. Therefore, we recommend for this district purification by aeration as described in this report as being
79 most economical and advantageous. Even this treatment will probably be unnecessary until the proposed drainage

system shall have been developed to at least one-half of its ultimate capacity.

Details of the project are given in the special report dated November 18, 1910.

Borough of Richmond Drainage District.*—This district includes all of Staten Island with an area of 36,623 acres, shaped roughly in triangular form with its vertex to the south and its greatest length from the vertex to near the centre of the base at the outer end of he Kill von Kull, on a line running northeast and southwest. It is bounded on the north by the Kill von Kull and the Upper Bay; on the east by the Narrows and the Lower Bay; on the south by the Lower Bay and on the west by the Arthur Kill. The total length of coast line is 36 miles, of which 18 miles border on the two Kills and 5 miles on the Upper Bay. Both Kills are now polluted by sewage from the cities of New Jersey to an extent which probably makes further discharge of sewage into them inadmissible. Tidal and current data are meagre, but the following discussion of the circulation in the Arthur Kill, based on the best information obtainable, confirms this opinion. An examination of the tidal curve of the current charts in Appendix No. 9 of the report for 1886 of the U. S. Coast and Geodetic Survey shows that the tide has risen to 1.51 above mean low water at the beginning of the flood currents and that the plane of the water rises to high water (+4.1) and falls to an elevation of +2.35 before the current begins to run ebb.

It is estimated that the amount of water in the Arthur Kill below the low water plane is about 1,973.5 million cubic feet; that the tidal area is about 123.34 million square feet; and that the ebb and flood flow through the cross-section at Elizabethport is 319.0 million cubic feet.

TABLE 24. SHOWING DATA FOR ARTHUR KILL.

Area.		Elevation at beginning of	Maximum or minimum elevation.	Elevation at end of period.	Tidal area, million sq. ft.	Tidal prism volume, million sq. ft.	Total volume at end of period, million cu. ft.
P-Arthur Kill	Flood	+1.5	4.1	2.35	123.34	289.9	2,263.4
P′ " "	Ebb	+2.35	0.0	1.50	123.34	185.0	2,158.5

Let M = clean water from the Lower Bay
Let K = water received from the Kill von Kull or Newark Bay
Let n = tide under consideration, flood or ebb
n-1 = the previous tide, ebb or flood
Then P_n = 2,263.4 million cu. ft. = 1,839 5 million cu. ft. (P'_{n-1}) + 423.9 million cu. ft. (M) = 8 28% (P'_{n-1}) + 18.72% (M)
= .8522 P'_{n-1} + 423 9 million cu. ft. (M)
P'_n = 2,158.5 million cu. ft. = 839.5 million cu. ft. (P_{n-1}) + 319.0 million cu. ft. (K) = 85.22% (P_{n-1}) + 14.78% (K) = .8128 P_{n-1} + 31.80 million cu. ft. (K)

*See map of Richmond Drainage District following p. 182.

80 Under present conditions it is estimated that the amount of sewage emptied into Arthur Kill amounts to 18.5 million gallons in 24 hours or 0.623 million cubic feet in 6 hours. Using this value in the above formulæ we get the following approximate figures for summer conditions:

Area.	Dilution ratio.	Per cent. of oxygen present. Without reaeration.	With reaeration.
P	1 in 127	76.5	86.9
P'	1 in 105	71.5	72.0

If the sewage from the Borough of Richmond be added to the sewage now discharged into the Kill from New Jersey, the figures will be as follows:

Area.	Dilution ratio.	Per cent. of oxygen present. Without reaeration.	With reaeration.
P	1 in 98	69.4	69.9
P'	1 in 76	60.6	61.1

The waters of the Upper Bay are so intimately connected by circulation with the waters of the Hudson and East Rivers that no increased pollution there is permissible. The Lower Bay, however, has its tidal prism filled and emptied in each tidal period from and into the waters of the ocean and has a capacity for sewage reduction greater than is necessary for all of the areas of its drainage basin. The safe points for the discharge of unpurified sewage from Staten Island are then into the deep channel of the Narrows and into the Lower Bay at those points lying near the channels of the bay through which the circulation of its waters takes place, including the lower half of the coast line between Great Kills and the southern end of the island.

The configuration of the land in Staten Island is not such as to render the concentration of the sewage and its discharge at the points named a simple matter. The natural drainage is to the east into the Lower Bay and to north and west into the Kill von Kull and the Arthur Kill. The divide between the two watersheds is a bold ridge. At the north it rises abruptly from the water to a height of 200 feet opposite the entrance to the Kill von Kull. From this point it runs slightly west and south with steep side slopes and gradually increasing elevation until about 4 miles from its northern extremely it attains a height of over 400 feet. It then inclines to the southwest and two miles further on drops to a height of 50 feet and gradually rises again to an average height of 100 feet, terminating near the south part of the island. The gap mentioned above affords a means of leading the drainage from a large part of the north watershed into the Lower Bay without the necessity for expensive tunnelling.

81 Along the Arthur Kill there are extensive areas lying at an elevation of less than 10 feet above mean sea level, which must

be drained into the Arthur Kill, unless expensive pumping plants are installed. The general configuration of the north watershed is such that an economical design will require minor lifts and long trunk lines, so as to permit of sewer discharge without purification, but the drainage system as projected has been designed with a view to a minimum expense for installation and operation.

The future population has been estimated at 25 per acre; the volume of sewage at 125 gallons per capita; ground water flow is assumed to be 0.003 second-feet per acre; other assumptions are similar to those of the other districts.

Seven outfalls are projected. The first serves the north and northeast shores and discharges into the deep water of the Narrows near the Quarantine Station. The second serves the area to the west of the ridge lying above the 50-foot contours and also the area east of the ridge above the 40-foot contours between the Narrows on the north and Great Kills on the south. The third serves the low land about Great Kills and discharges off shore in 12 feet of water by means of a pressure main.

The fourth serves the eastern slope of the ridge between Great Kills and Princes Bay and discharges 800 feet off Seguine's Point at the head of Princes Bay in a 21-foot channel running parallel to the shore. The fifth serves the south end of the island and discharges 1,600 feet off shore below Princes Bay into the same channel. A portion of the sewage discharged here will have to be pumped over the ridge whence it will discharge by gravity and another portion will have to be lifted from a sump to the gravity discharge main.

No purification will be required for the sewage discharged from these five outfalls.

The two areas of low land along the Arthur Kill will have to be provided with distinct systems, each concentrating in a sump, from which the sewage must be lifted and after partial purification, discharged into the Arthur Kill. Complete purification will be unnecessary, since once the waters have reached the Lower Bay there will be ample capacity there to receive and care for the sewage carried by them.

Full details of the system as projected are contained in the special report dated February 15, 1911.

Bronx District Sewage—Since the drainage from this district can be carried to the East River at points near Throgs Neck, where the capacity of the waters is ample to care for it without purification, it has not been deemed necessary in the limited time at our disposal to do more than indicate the possible points of concentration and discharge.

The drainage lines recommended for all of the districts are shown on the accompanying map.

82 **Chapter V.**

In making the studies reported in the preceding chapters, the lack of means to obtain more accurate maps of the districts reported on, more complete data as to the volume of sewage now being discharged into the various parts of the harbor, greater detailed knowledge of current velocities and a more complete set of determinations of the average existing pollution were keenly felt by the authors. They feel confident, however, that true conclusions can be derived from the work accomplished.

Table 6 in Chapter I shows clearly how pollution in one part of the harbor affects the remaining areas. At the end of the flood current period the Hudson below Ninety-sixth street is filled by waters of which 3 per cent were in the Lower Bay at the end of the last ebb and 97 per cent in the Upper Bay at the same tidal period; the Hudson between Ninety-sixth street and Spuyten Duyvil received 17 per cent of its contents from waters of the Upper Bay of the preceding ebb and 83 per cent from below Ninety-sixth street; the East River, from the Battery to Hell Gate, is filled with the waters of the Upper Bay of the last ebb tidal period; the waters of the East River beyond Hell Gate are 7 per cent from the Upper Bay of the preceding ebb, 41 per cent from the lower East River of the preceding ebb, 50 per cent from its own waters of the preceding ebb and 2 per cent from the Harlem of the preceding ebb; and the Harlem is made up 25 per cent from its own waters of the preceding ebb, and 75 per cent from the waters of the Hudson of the same period. During this period the flow has been from Sandy Hook toward Throgs Neck, via the East River direct and via the Hudson, Harlem and East Rivers; the clean sea water entering but for a short distance, the remainder of the flow being composed of water more or less polluted from its earlier stay in the harbor.

During the ebb period the flow is in the opposite direction. Pure water enters from the Sound and penetrates but a short distance into the East River. Thus at the end of the period it is seen that only 20 per cent of the volume east of Hell Gate is pure, the remainder being of water which has been in the area for from 6 to 12 hours longer; the Harlem contains 65 per cent of water from the earlier East River flood and 35 per cent from its own preceding flood volume; the Hudson above Ninety-sixth street is composed 81 per cent of water which had been in it in the second preceding ebb, 3 per cent of Harlem water of the preceding flood and 16 per cent of water from the Hudson above Spuyten Duyvil; below Ninety-sixth street the waters are 25 per cent preceding ebb, 14 per cent from the Hudson above of the preceding ebb and 60 per cent of those of the preceding flood plus 1 per cent of Harlem water of the preceding flood; the Upper Bay is a mixture from the Hudson and East Rivers and from the Kill von Kull.

The resultant movement of the circulation is towards Sandy Hook, but this movement is not continuous nor at a fixed rate (the formulæ being based on mean tidal conditions). During all of the time of fluctuation through the various channels each cubic foot of water

is giving up oxygen in sewage reduction, with no accessions save the small amount received by reaeration.

A study of Table 9 shows the danger of continuing longer the present system of conveying sewage to the nearest waterway
83 and there discharging it without treatment. Tables 9, 10 and 11 show that, while the capacity of the harbor waters to receive and reduce sewage without undue pollution is ample for the present population, such is the case only when the sewage is discharged near the harbor entrances; and further that even with full diffusion, it is unsafe to discharge sewage into the river waters without treatment. Either conveyance to the harbor entrances or treatment before discharge is feasible, but either course would entail a heavy expenditure. The selection of the more economical can not be made without further and detailed investigation.

The effect of the pollution of the Hudson River above the limits of the City on the waters of the upper Hudson and the Harlem is shown clearly in the formulæ of Table 6, and in the oxygen percentages of Tables 9 and 10. Table 10 shows that were it not for the pollution of the Hudson above the city limits, the average oxygen contents of all of the harbor waters would be made over 60 per cent. of saturation by partial purification of the sewage now discharged into the Hudson and Harlem Rivers alone. Table 11 shows this even more forcibly.

The investigations into the method of partially purifying the sewage by aeration, described in detail in Chapter III, show the possibility of obtaining at small cost and with a plant requiring little space a degree of purification ample for sewage emptying into waters under conditions similar to those of Jamaica Bay and of the Arthur Kill. The authors feel sufficient confidence in the results obtained to warrant them in recommending that the existing Twenty-sixth Ward Pumping Station in Brooklyn be fitted with a plant for sewage treatment by this method, with the belief that with greater experience the method can be further developed, so as to warrant a more extended application.

The studies of the harbor capacity warrant them further in recommending that no purification be now made of sewage from the Flushing, Corona and Bronx Districts discharged into the deep water of the channels of the East River at points east of Riker's Island.

In order to avoid a local nuisance, from such discharge, it is necessary that a complete diffusion of the sewage be made immediately on discharge. They know of no method now in use which will secure such diffusion and recommend that experimental work be carried on to develop the best form of outlet for this purpose.

Finally, they would state that it is their belief that radical measures are now necessary for the prevention of injury to the harbor by sewage pollution. Since to be effectual such measures must be applicable to all communities from which sewage is discharged, they believe that joint action in the matter is necessary by the States of New York and New Jersey; that a standard of purity should be adopted for the harbor waters; that the measures necessary to attain

and maintain that standard should be determined; and that such further action as may be necessary to carry such measures into effect should be taken.

Respectfully submitted,

W. M. BLACK.
EARLE B. PHELPS.

New York, February 16, 1911.

84 *Appendix.*

Determination of the Rate of Absorption of Atmospheric Oxygen by Water.

In the text of this report brief reference was made to the relationship existing between time, depth and initial degree of aeration and the amount of atmospheric oxygen absorbed by a given body of water. The mathematical derivation of these relationships and the technique involved in the experimental determination of the diffusion coefficient will be given here in full.

Mathematical.

Assume a column of water, not fully saturated with dissolved oxygen, and exposed to the atmosphere at one end. This is essentially the condition found in a lake.

An infinitely thin layer at the surface of the water becomes saturated with oxygen in an infinitely short time, i. e., at once. This layer can absorb no more oxygen until a portion of that which it contains has passed, by diffusion, to the deeper layers. The rate of absorption therefore is governed wholly by the rate at which oxygen diffuses through the liquid.

The diffusion law:

Fick's law of hydro-diffusion (Nernst, Theoretische Chemie, 2nd German Ed., p. 150) expresses the rate of diffusion of dissolved substances in terms of the concentration gradient as follows:

$$\frac{ds}{dt} = -aq \times \frac{dc}{dx}$$

ds is the amount of substance passing any point, x, through a cross-sectional area, q, in time, dt, when the concentration gradient is $\frac{dc}{dx}$; c is the concentration at any point, varying with x, and a, is a constant for the given substance at given temperature called the coefficient of diffusion.

The first problem is to derive from the fundamental equation an expression which will permit the experimental determination of "a."

At the point x + dx the concentration gradient becomes

$$\frac{dc}{dx} + \frac{d}{dx}\left(\frac{dc}{dx}\right) dx = \frac{dc}{dx} + \frac{d^2c}{dx^2} \cdot dx$$

and the amount of substance passing that point is determined by

$$\frac{ds}{dt} = aq\left(\frac{dc}{dx} + \frac{d^2c}{dx^2} \cdot dx\right)$$

The difference between the amount passing point x and that passing point x + dx is the increase in the amount of substance present in the volume qdx during the time dt. This is

$$aq \frac{d^2c}{dx^2} \cdot dx$$

85 The increase in concentration in this section is the increase in amount divided by the volume, or

$$\frac{dc}{dt} = \frac{d^2c}{dx^2}$$

which states that the rate of change in concentration of dissolved substance occurring at any point, x, is proportional to the differential of the concentration gradient or the second differential of the concentration itself with respect to the distance. If the gradient be uniform, differential zero, there is no change in concentration occurring at any point.

It will be convenient to express concentration in the usual form, milligrams per liter, or parts per million, distances in centimeters and time in hours which will result in giving the constant "a" a fixed value. As thus defined, "a," the diffusion coefficient, is the rate per hour at which the concentration of dissolved substance is changing at any instant, under the condition that the concentration gradient is changing at a rate of one milligram per liter, per centimeter *per centimeter*.

The relations are almost exactly those existing in the case of the transfer of heat through a conductor.

The solution of the differential equation given above requires the establishment of certain limiting conditions, although the equation itself applies to all conditions.

Case I.

The water contains no oxygen at the start. A surface film becomes saturated instantly, concentration, s. The column has a definite length (L).

to solve $$\frac{dc}{dt} = a \frac{d^2c}{dx^2} \qquad (1)$$

Under the given conditions when

$$t = o \qquad c = o \qquad (2)$$
$$x = o \qquad c = s \qquad (3)$$
$$x = L \qquad \frac{dc}{dx} = o \qquad (4)$$

The reason for applying condition (4) requires discussion. Since no oxygen is passing the closed end, the gradient obviously becomes zero at that point, after the oxygen has diffused to the end of the column. But mathematically a gradient of zero at $x = L$ implies a positive gradient at all other values of x less than L, which in turn implies some oxygen at all points from the start, or, in other words, an infinite rate of diffusion for the first diffusing molecule. This conception could only be realized if the diffusing gas itself were infinitely divisible. At concentrations with which we deal analytically matter is practically divisible in this way and the inconsistency vanishes. After deriving the experimental constants involved it will be possible to calculate the actual magnitude of the inconsistency noted.

A general solution of equation (1) is

$$c = -e^{-ab^2t} \sin bx + \text{const.}$$

or any multiple of such a term or the sum of any series of such terms.

Substituting condition (3) we have

$$\text{const.} = S$$

Giving

$$c = -\epsilon^{-ab^2t} \sin bx + S$$

Differentiating and substituting condition (4) we obtain

$$\frac{dc}{dx} = -\epsilon^{-ab^2t} \cdot b \cdot \cos bL = o$$

which is true if

$$b = \frac{(2\eta + 1)\pi}{2L}, \ \eta \text{ being any positive integer.}$$

Finally to satisfy condition (2) we have

$$S = \sin bx$$

Since the general solution given above may contain a series of terms of the same form as the one developed, Fourier's series is available for determining this function.

We may write

$$S = \frac{4}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} \sin \cdot (2\eta + 1)\, y \text{ by Fourier's series.}$$

Put $y = \frac{\pi x}{2L}$, and the expression, $\frac{2\eta+1}{2L} = b$,

$$S = \frac{4}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} \sin \cdot bx$$

Since this expression is the sum of a series of multiples of sin bx, it may be substituted for sin bx in the general solution. Making all substitutions:

$$c = s - \frac{4}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} \cdot \epsilon^{-ab^2t} \cdot \sin bx$$

when $b = \frac{2\eta+1}{2L}$, η being any integer.

This equation expresses the relation existing between concentration of dissolved oxygen at any point, (c), distance of that point from the exposed surface, (x), and time of exposure, (t). With a fixed time it is the equation of the concentration curve, giving concentrations at all points from surface to bottom. Experimentally we can best determine the average concentration in the column. The determination of a concentration at any given depth

4085

DARK PAGE BLEED THRU

would be analytically difficult. We may, therefore, determine from this equation the total amount of oxygen contained in a given differential volume and by the summation of all these amounts arrive at an expression for the total amount of oxygen in the column.

Let the area of the cross section of the column be q. The volume of a differentia strip will then be q dx. The amount of oxygen in this volume is the concentration times the volume or

$$dO = cqdx = Sqdx - \frac{4\,Sq}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} e^{ab^2t} \sin bx \cdot dx$$

We may now obtain the total amount of oxygen in the column by integrating this equation between limits, o and L;

$$O = Sq \int_L^o dx - \frac{4\,Sq}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} \cdot e^{-ab^2t} \int_L^o \sin bx \cdot dx$$

$$= SqL - \frac{4\,Sq}{\pi} \sum_{\eta=\infty}^{\eta=0} \frac{1}{2\eta+1} \cdot e^{-ab^2t} \cdot \frac{1}{b}$$

Substituting the value of $\frac{1}{b}$ and simplifying

$$O = SqL\left(1 - \frac{8}{\pi^2} \sum_{\eta=\infty}^{\eta=0} \frac{1}{(2\eta+1)^2} \cdot e^{-ab^2t}\right)$$

But SqL represents a condition of saturation in the volume qL, so we may express the oxygen in terms of "per cent. saturation" by dividing by the saturation value, SqL, and multiplying by 100.

$$O\ (\%\ Sat) = 100 - \frac{800}{\pi^2} \sum_{\eta=\infty}^{\eta=0} \frac{1}{(2\eta+1)^2} e^{-ab^2t}$$

Whence we derive as a working formula

$$D.\ O. = 100 - \left(81.06\, e^{-K} + 9.007\, e^{-9K} + 3.242\, e^{-25K} + 1.654\, e^{-49K} - - - -\right)$$

In which $K = \frac{a\,t\,\pi^2}{4\,L^2} = \frac{2.467\,a\,t}{L^2}$

e = 2.718, base of natural logs.
a = diffusion coefficient (to be determined).
t = time in hours.
L = length of column in centimeters.

Case II.

Similar to I. except that the concentration at the start is B, throughout.

To solve

$$\frac{dc}{dt} = -\frac{d^2c}{dx^2} \qquad (1)$$

Under the conditions

When $t = o$ $\quad c = B$ (2)

$x = o$ $\quad c = S$ (3)

$x = L$ $\quad \frac{dc}{dx} = o$ (4)

The procedure is exactly the same as in I. until condition (2) is treated. Here we get

$$S - B = \sin bx$$

When the final equation becomes

$$C = S - \frac{4(S-B)}{\pi} \sum_{\eta=\infty}^{\eta=o} \frac{1}{2\eta+1} \cdot e^{-ab^2t} \sin bx$$

This equation is integrated in the same way, giving

$$O = SqL - \frac{4(S-B)q}{\pi} \sum_{\eta=\infty}^{\eta=o} \frac{1}{2\eta+1} e^{-ab^2t} \cdot \frac{1}{b}$$

Whence the final working formula becomes

$$O(\%\text{ sat.}) = 100 - \left(1 - \frac{B}{100}\right) \cdot (81.06\, e^{-K} + 9.007\, e^{-9K} + 3.242\, e^{-25K} + 1.654\, e^{-49K} - - -)$$

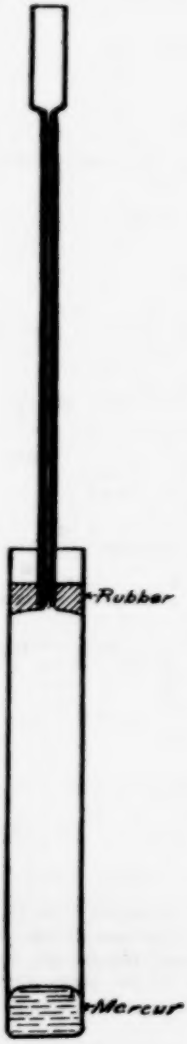
$$= 100\left[\left(\left(1 - \frac{B}{100}\right) \cdot 81.06 \cdot \left(0.779 + \frac{0.105}{9}e^{-K} + \frac{0.0019}{25}e^{-K} - - -\right)\right)\right]$$

B = initial value of dissolved oxygen.

D = final value of dissolved oxygen.

K = a constant for each experiment $= \frac{\pi^2 a t}{L^2}$

t = time in hours.



L = depth in centimeters.

a = diffusion co-efficient.

The determination of K from this equation, with O, S and B given is not possible by any workable method. The sum of the series was therefore determined with varying values of K and the results plotted. It was observed that by plotting the logarithms of the sums against corresponding

Apparatus
Used in Determining
Diffusion Coefficient.

Diagram I
(Appendix)

76—Ex. 136

The determination of K from this equation, with O, S and B given is not possible by any workable method. The sum of the series was therefore determined with varying values of K and the results plotted. It was observed that by plotting the logarithms of the
90 sums against corresponding values of K the result was nearly a straight line for the higher values. This method of plotting was therefore employed. This line deviates from a straight line more and more in the lower values when the solution requires a greater number of terms of series. Forty terms of the series were employed in the computation at K=.0001. In the range over which the plot will be of greatest practical value, the determinations are quite accurate and interpolations can be satisfactorily made.

Experimental.

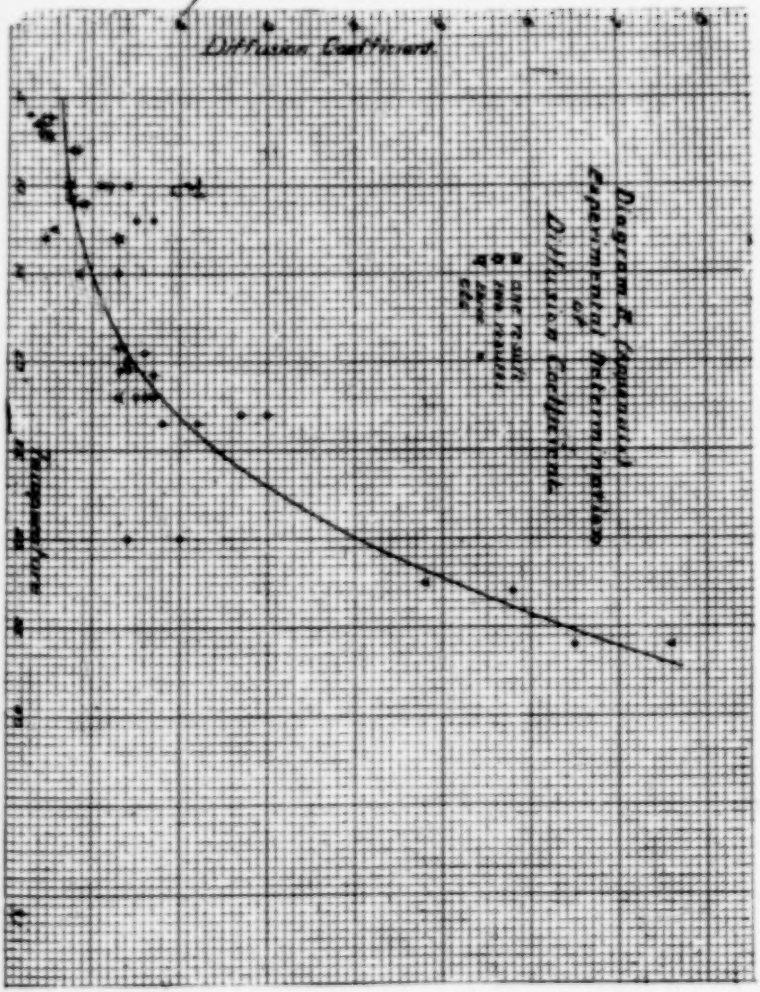
The experimental determination of a is now made possible. If a column of water, whose initial content of oxygen is known, be exposed to the air for a definite time and the final content of oxygen be then determined, data are available for calculating the coefficient a. It is essential that during the test there shall be no circulation of the water within the tube. The rate of absorption is so slow that results of maximum accuracy are obtainable only in tubes of short length, exposed for a few hours. Lengths of 7 to 8 centimeters were found most satisfactory. To test the depth factor, L, in the formula a few determinations were made in tubes of four centimeters. The determination of dissolved oxygen in such small volumes required more delicate methods than those in common use. The method which was finally adopted is the result of a long investigation of possible methods. It depends upon the reoxidation of decolorized indigo.

A detailed description of the method employed is as follows: A quantity of "iron-excelsior," made of fine iron turnings was placed in a flask of water which was then vigorously boiled. After boiling for some time the flask was connected with a hydrogen generator through an absorption bottle containing pyrogallate solution, and the flame was removed. The flask was allowed to cool in this condition over night. The next morning water could be drawn which contained three to ten per cent. of the saturation value of dissolved oxygen. Water with less oxygen than this is exceedingly difficult to prepare.

The apparatus employed for the determination of absorption is shown in the sketch. It consisted of a test tube, into which a rubber stopper was fitted with extreme care, so as to slide plunger-fashion within the tube. This stopper was wet with a very dilute caustic solution to assist the sliding. The capillary glass tube passed through the stopper to its inner surface which was concaved slightly. The tube was expanded at its upper end into a straight-sided funnel. Two etched lines, one near each end of the tube, marked off a definite volume.

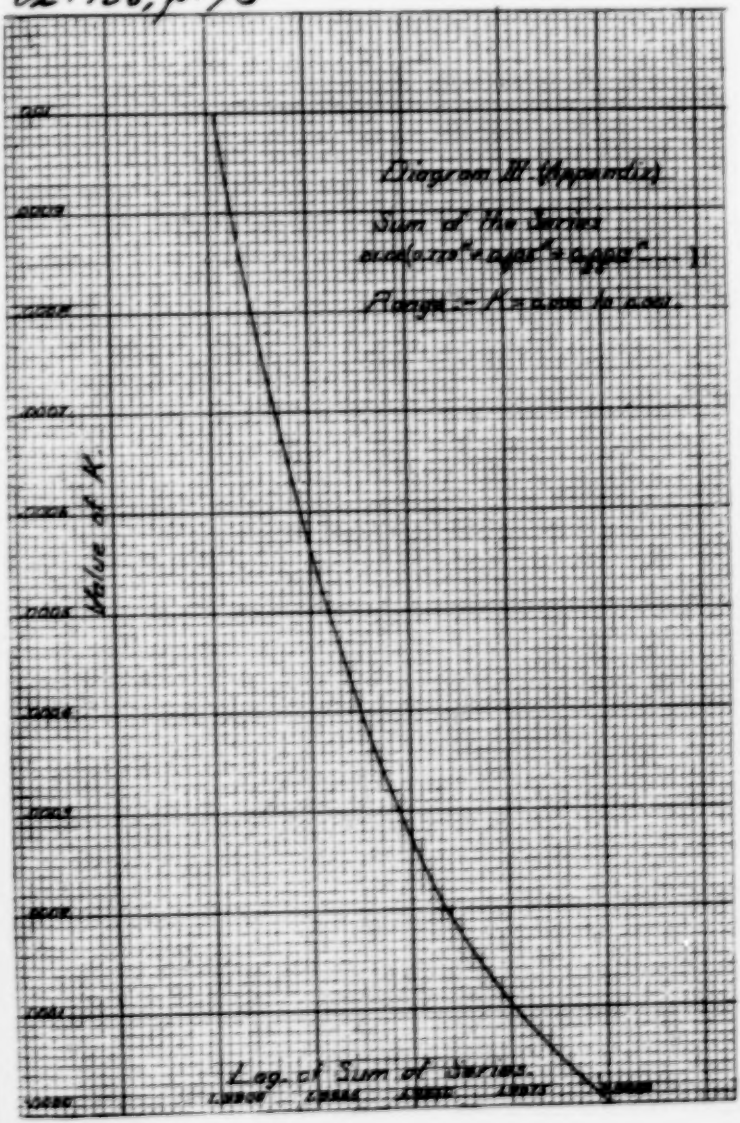
The tube was filled with mercury to slightly above the lower line. The stopper was then forced into the mercury, expelling all air and forcing mercury through the capillary to the upper funnel. A si-

phon from the bottom of the flask described above was then inserted into the funnel, its end projecting below the mercury, and the water was allowed to run for a minute or two, overflowing from the funnel. Then while the water was still running, and overflowing, the stopper was slowly withdrawn, allowing a small stream of water to enter the tube. In this way the water was transferred without contact with the air.



When the stopper had reached the upper mark, its movement was stopped and, while the water was still flowing above, a drop of
91 mercury was added to the funnel to seal the capillary. The tube was then removed, the funnel emptied of water and dried and the whole apparatus set in a large water tank, previously brought to the temperature desired for the experiment.

The tube was left there one hour to acquire a uniform temperature. Then while still immersed nearly to its upper edge, the tube was exposed to the air by the removal of the stopper and capillary. The time was noted and during the exposure the oxygen in a set of "blank" tubes was determined. These blanks were prepared exactly as described here, but were not exposed. They furnished the initial value, B, in the formula.



After an exposure of from one-half to four hours the tubes were again plugged with the same stoppers and capillaries, the stopper being forced in until the capillary was filled and a seal of mercury was applied as before. The tube was now ready for an oxygen determination.

A solution of indigotine or soluble indigo was placed in the funnel, above the mercury seal. A solution of sodium hydro-sulphide was added in excess to completely reduce and decolorize the indigo. A glass tube connected with a carbon-dioxide generator was inserted into the funnel and a stream of carbon-dioxide blown through the reduced indigo. This gas, by accumulating over the liquid prevented the too rapid oxidation of the indigo by the air, at the same time there was enough oxygen in the carbon-dioxide to oxidize the indigo slowly and uniformly. Finally a faint blue color would return in the tube and when this color matched a standard tube which had been prepared of known value, the stopper was raised and the indigo added to the water. A new mercury seal was put in, the tube well mixed and put aside. The oxidation of the indigo was almost instantaneous but proceeded at a decreasing rate for some time. While still sealed from the air this tube was then compared with a set of standards in similar tubes, the latter having been prepared by diluting a standard indigo solution which was made up to match a single test made upon a saturated water of known oxygen content. Repeated tests of this method upon waters of known value showed that it could be relied upon to give results with these small amounts of water, that were free from reagent corrections and of much greater accuracy than could be had from the older method.

Value of N
Sum of N Series.

Results.

One hundred and fourteen tests were made at temperatures ranging from 6 degrees to 30 degrees, with tube lengths of from 3.8 to 8.4 centimeters and with exposures of from one-fourth to four hours. The results have been plotted in Diagram II., values of a being shown in relation to temperature. To avoid confusion, sets of closely agreeing results have been averaged and the average values shown as one value, the number of determinations included in the average being indicated by the number of radial lines about the circle. The values are somewhat scattering, and a closer analysis indicates that some unknown factor is involved. Exceedingly concordant results are readily obtained upon any one day, while upon the following day another group of concordant results will be obtained differing from the first. Barometric corrections were later applied without
91½ relieving the situation. It is quite likely that humidity conditions would explain the irregularities. Considering the variations in depth, time, and initial values, that were employed the results on the whole are satisfactorily uniform and the curve which has been drawn, being deduced from such a large number of results, probably gives a value of the diffusion coefficient at any temperature which is not far from the actual truth.

Within the range of values which have been employed in the computations in the text errors resulting from the maximum divergence of individual tests from the average value of the curve are less than 5 per cent. at the five-foot depths and less than 2 per cent. at the twenty-foot depths.

(Here follow diagrams II, III, and IV, marked pages 92, 93, and 94, Complainants' Exhibit 136.)

95 *Special Report on the Corona Drainage District Submitted to the Board of Estimate and Apportionment June 17, 1910.*

96 CHIEF ENGINEER'S OFFICE,
BOARD OF ESTIMATE AND APPORTIONMENT,
CITY OF NEW YORK, June 10, 1910.

Hon. William J. Gaynor, Mayor, Chairman of the Board of Estimate and Apportionment.

SIR: Herewith is transmitted a report from Colonel William M. Black and Professor Earle B. Phelps, bearing date of May 24, 1910, relative to the treatment of the drainage of that portion of the Borough of Queens north of the ridge or backbone of the island, and extending from Flushing Creek to Newtown Creek.

The investigation of the matter of reference has been made pursuant to the authorization of the Board of November 12, 1909, under which Colonel Black was engaged to advise relative to the treatment of the drainage problem of the city in so far as it related to the pollution of the adjacent waters.

The result of the investigation of this problem for the territory between Flushing Creek and Little Neck Bay was made the subject of a report which was presented at the Board meeting of April 22, 1910, and which was thereupon referred to the President of the Borough of Queens for general guidance in the design of sewers for the locality. At this time attention was called to the fact that to establish its feasibility the plan submitted had been made to include a general subdivision of the territory considered into drainage districts and also the planning of the main trunk lines, but that the latter was based on making provision only for the sanitary flow with which the investigation was primarily concerned. It was suggested at this time that it would seem desirable to provide in the drainage plan for the removal of both the sanitary and storm water flow in a combined system of sewers, and that if such treatment were to be adopted it would probably be necessary to modify the plan in many particulars, although it was believed that the general scheme could be applied.

The report now presented relates to an area of about 14,535 acres, for which the sanitary requirements only have been considered other than in so far as an excess of capacity may have been provided to meet future growth and which may, for a limited time, be utilized for removing the surface water.

In general, the plan contemplates two main trunk sewers, these providing, respectively, for the independent drainage of most of the First and Second Wards, these sewers meeting at the junction of Riker avenue and Theodore street, from which point the main outlet would extend out to deep water off the foot of the latter street. This outlet is stated in the report to have been selected, having in view the possibility of extending it by tunnel to Rikers Island in case it should be ultimately found necessary to install purification works.

It has not been found practicable to incorporate in the plan that

97 portion of Long Island City immediately adjoining the water front and an area of considerable extent at the head of Newtown Creek, both of which are at such low elevation as to require pumping. The sewers in the former section have been largely constructed and it is evidently believed that their use can be continued for some time in the future. It is also understood that a portion of the low area may possibly find an outlet through sewers in the Borough of Brooklyn. A small area in the vicinity of Bowery Bay is also found to be of too low an elevation to secure a gravity outlet, but in the remaining subdivisions of the drainage area it is understood that no pumping will be required.

A number of sewers have already been built in the Elmhurst section, and the plan makes provision not only for continuing their use but also that of the purification plant already built until such time as it is found practicable to carry out what is suggested as the ultimate plan.

In the report it is pointed out that the studies relative to the capacity of the harbor to absorb sewage are still in progress and have not yet advanced far enough to warrant any recommendation in the matter. Attention, however, is called to the desirability of supplementing this work with independent investigation and experiment at various points which would bring out information not now available relative to the requirements which must be met before reaching a final determination as to the extent of the purification which will undoubtedly at some time be required.

I would recommend that a copy of this report be sent to the Presidents of the Boroughs of Brooklyn and Queens to be used for their guidance in the development of the drainage plan for the territory affected.

Respectfully,

NELSON P. LEWIS,
Chief Engineer

98

May 24, 1910.

Mr. Nelson P. Lewis, Chief Engineer Board of Estimate and Apportionment.

SIR: In connection with our general studies of the sewerage problems of certain portions of Greater New York, we beg to submit herewith a second report, which deals with the main drainage problem of that portion of Queens Borough lying between Flushing Bay, Newtown Creek, the East River, and the division line between Queens and Brooklyn. For purposes of convenience and identification we have designated this district the "Corona Drainage District." Reference to the accompanying map marked "Corona Drainage District"* will facilitate the discussion which follows.

*Omitted. See general map of Drainage Districts of Jamaica, Corona, Flushing, and Westchester, p. 148.

Divisions of the Drainage District.

For the purposes of this study we have divided the above designated district into eighteen drainage areas, numbered respectively 1 to 18, of which areas Nos. 3, 4, 5, 9, 10 and 11 are subdivided into two sub-areas designated by *a* and *b* respectively; and areas Nos. 6, 8 and 13 are similarly subdivided by *a*, *b* and *c* respectively. In the map the division lines between these areas are indicated by heavy dotted lines. Contour lines at 20-foot intervals are shown, but these are only approximate, by reason of the lack of detailed topographic surveys and of available time and funds for making such surveys, which has been commented upon in our first report. Our proposed sewer lines are indicated in red, and other features are sufficiently described in the legend. Estimates of future populations have been made upon a basis of either twenty-five or fifty persons per acre, depending upon the location of the area in question and the character of the country. The drainage areas dealt with are approximately as follows:

Area No. 1. This area is bounded on the south by a crest line which is practically the division line between two wards; it extends on the east to a crest line which has already been identified as the westerly boundary of the low level area in the Flushing Drainage District, and on the north to a crest which parallels the first crest mentioned for a distance of about seven thousand feet. Its westerly boundary is a broken line which has been determined by the requirements of existing sewer assessment districts. It contains 2,343 acres, from which we have deducted 793 acres of parks and cemetery land. The estimated future population is 38,750.

Area No. 2. This is a small area lying between the northerly boundary of No. 1 and the 20-foot contour line which separates it from the low level area of the Flushing Drainage District. It extends on the west to Dry Harbor road. It contains 482 acres, with an estimated future population of 24,100.

Area No. 3. This is a small area bounded practically by Metropolitan avenue, Dry Harbor road and North Hempstead Plank road on the south, east and north, respectively, and on the west by the natural crest line as indicated. It contains 500 acres, with an estimated future population of 25,000. It is subdivided into two subareas of 360 and 140 acres with 18,000 and 7,000 estimated future populations, respectively.

Area No. 4. This area lies to the north of No. 3 and extends to Woodside and Broadway on the north, and to Dry Harbor road on the east. Its westerly boundary is a crest line just west of Fiske avenue. It is further divided by a crest line running northeast, as shown. It contains 613 acres, with an estimated future population of 30,650, of which 266 acres and 13,300 population are included in Sub-area *a*, and 347 acres and 17,350 population are included in Sub-area *b*.

99

Area No. 5. This area lies to the northwest of the low level area of the Flushing District already described, and above the 20-foot contour line. It extends on the north to Jackson avenue and on the

west to a crest line running north and south as shown. It is subdivided as shown. It contains almost all the Corona section, having a total area of 959 acres, with an estimated future population of 47,950, of which 761 acres and 38,050 population are included in sub-area *a*, and 198 acres and 9,900 population are included in sub-area *b*.

Area No. 6. This area lies to the northwest of No. 5, extending to Flushing Bay on the northeast and following the 20-foot contour line on the northwest. It extends on the west to a crest as shown and on the south to Woodside. It is subdivided into three sub-areas: Sub-area *a* comprising the southeasterly half of the whole area; *c* comprising a strip about 1,500 feet in width along Flushing Bay; and *b* the remainder. It contains altogether 1,154 acres with an estimated future population of 57,700, of which 610, 359 and 185 acres, and 30,500, 17,950 and 9,250 population are included in sub-areas *a*, *b* and *c*, respectively.

Area No. 7. This area is a narrow winding low-level strip lying to the northwest of No. 6, situated entirely below the 20-foot contour line. It comprises practically the low land surrounding the small inlet from Flushing Bay to the southeast of Sanford Point. It contains 381 acres, with an estimated future population of 19,050.

Area No. 8. This area is a similar narrow strip lying to the northwest of No. 7, extending to the waterfront on its easterly end and to a crest which is practically a projection of this same waterfront as far west as Wilson avenue. It includes also a larger area to the west of Nos. 6 and 7, bounded practically by Newtown road and Woodside. It is subdivided into three sub-areas. It contains 811 acres, with an estimated future population of 40,550, of which 569, 126 and 116 acres and 28,450, 6,300 and 5,800 population are included in sub-areas *a*, *b* and *c*, respectively.

Area No. 9. This area lies to the northeast of No. 8 and is bounded on the east by the 20-foot contour which practically parallels Winthrop avenue, and on the west by crest line which follows Ditmars avenue closely. It extends on the north practically to the East River. It is subdivided into two sub-areas and contains 403 acres, with an estimated future population of 20,150, of which 207 and 196 acres, and 10,350 and 9,800 population are included in sub-areas *a* and *b*, respectively.

Area No. 10. This is a low-level area lying entirely below the 20-foot contour. It extends from Area No. 9 to the East River and includes on the east a narrow strip of shore front extending to Sanford Point; on the west a similar strip extending as far as Astoria. It is subdivided into two sub-areas. It contains 394 acres, with an estimated future population of 19,700, of which 197 acres and 9,850 population are included in each of the sub-acreas.

100 Area No. 11. This area lies to the southwest of No. 9 and in part to the north of No. 8. It extends also to the west in a narrow point to Noble avenue in the Ravenswood district. It is bounded on the northwest by the 20-foot contour, which separates it from No. 10, and by a straight line which is practically identical

with a continuation of that contour between Astoria and Ravenswood. The westerly point is bounded on the south by a crest line as shown. It is subdivided into two sub-areas. It contains 966 acres, with an estimated future population of 48,300, of which 374 and 592 acres and 18,700 and 29,600 population are included in sub-areas *a* and *b*, respectively.

Area No. 12. This area includes the waterfront from Astoria south and west to Newtown Creek. It is bounded on the east by a line which follows in general the 20-foot contour. It contains a portion of Astoria and all of Ravenswood and Hunters Point, with an area of 129,000 acres and an estimated future population of 64,500.

Area No. 13. This area lies between Areas Nos. 8, 11 and 12 as defined, and extends on the southeast to the crest line which runs in a southerly direction from the junction of Greenpoint avenue and Woodside to Newtown Creek. It is subdivided into three sub-areas. It contains 1,209 acres (of which 167 comprise parks and cemeteries), with an estimated future population of 52,100, of which 511,382 and 316 acres, and 25,550, 19,100 and 7,450 population are included in the sub-areas *a*, *b* and *c*, respectively. The 167 acres of park and cemetery are within sub-area *c*.

Area No. 14. This area is a narrow strip lying to the southeast of Nos. 8 and 13. It extends on the east to Area No. 4 and on the south to a line which follows closely the 30-foot contour. It contains 335 acres, with an estimated future population of 16,750.

Area No. 15. This area lies to the southeast of No. 14, extends on the north and east to No. 4, on the west to the Long Island Railroad, and on the south to a line which practically marks the 35-foot contour. It contains 501 acres, with an estimated future population of 25,050.

Area No. 16. This area lies to the southeast of No. 15 and to the southwest of No. 3. It is bounded on the south by a crest line extending in an east and west direction as shown. It contains 909 acres of which 236 acres comprise parks and cemeteries, and its estimated future population is 33,650.

Area No. 17. This area comprises a narrow strip along the Newtown Creek and southwest of Areas Nos. 13 and 15. It is bounded on the south by a line which is practically identical with Grand avenue. It contains 255 acres, with an estimated future population of 12,750.

Area No. 18. This is a large area lying in the southerly corner of the drainage district. It extends from the Borough line on the southeast to the crests which have already been described as bounding Areas Nos. 1, 2 and 16.

The acreage and estimated future populations of these eighteen drainage areas are tabulated below. The total area of the district is 14,535 acres and the total estimated future population 628,200. This district as defined includes an area of 756 acres with an estimated future population of 37,800 (comprising areas 15 and 17), which is now, or will naturally become, tributary to the sewers of Brooklyn Borough.

101

Area.	Acres.	Poulation (est. future).
1	*1,550	38,750
2	482	24,100
3	500	25,000
4	613	30,650
5	959	47,950

	13,339	628,200
Park and cemetery	1,196	
Total	14,535	

* Includes park and cemetery land.

General Scheme of Sewerage for the District.

A general description of the scheme of sewerage which we have provided for the entire Corona Drainage District will now be given. The final point of discharge, as now provided, will be in deep water in the East River at a point approximately 1,500 feet to the southeast of Berrian's Island. The question of some form of treatment of this sewage will be considered in a later report. Having in mind the possibility that purification to some degree may be found desirable, this point of final discharge has been so located that if necessary the entire discharge can be carried by tunnel to Riker's Island, where suitable purification works can be installed. To bring the sewage to this point, we have provided two main intercepting systems which, for convenience, we will designate the East Interceptor and the West Interceptor. The main line of the East Interceptor may be considered to start at the junction of Myrtle and Tompkins avenues in Area No. 18, to flow in a westerly direction through that area to the Borough line, thence in a general northeasterly direction along the natural valley line which carries it eventually completely through the center of the district to a point on Flushing Bay, and thence following the shore to the point of discharge.

A main branch of this interceptor starts at nearly the same point

between Areas Nos. 1 and 18 and flows through a second valley in a northeasterly direction to the low land near Flushing Creek, thence on the margin of this low land to the point of junction with the main line in Area No. 5.

The West Interceptor may be considered to start at the extreme southern point of Area No. 13*c*, and to run in a general northerly direction to the Pennsylvania Railroad yards, making a de-
102 tour around these yards and thence northeasterly, following approximately the 40-foot contour to the north corner of Area No. 9*b*, and thence southeasterly to the point of discharge. Trunk sewers, designated in general by the number of the area served, will enter these interceptors as follows:

Trunk No. 3*a* enters the main branch where it crosses Trotting Course lane. This trunk is composed of two branches, draining the two sides of Sub-area No. 3*a*.

Trunk No. 3*b* enters this same branch near the point of crossing North Hempstead Plank road, and drains Areas 3*b*, 4*a* and 2.

Trunk No. 14 enters the East Interceptor at the corner of Maurice and Thompson and drains Area No. 14 and a portion of 4*b*.

Trunk No. 5*a* enters this same interceptor at Sycamore avenue and drains the northerly portion of Area No. 5*a*.

Trunk No. 5*b* enters this interceptor at Flushing and Newtown Turnpike, and drains Area No. 5*b*.

Trunk No. 6*b* enters this interceptor at the northern end of Area No. 6*c* and by its two branches drains Area No. 6*b*.

Trunk No. 7 enters the interceptor at the same point and drains Area No. 7. It will probably be necessary to pump from this trunk into the interceptor.

Trunk No. 8*b* enters the interceptor on the Shore road and drains directly Area No. 8*b*. It extends to the southwestern corner of Area No. 7, at which point branches draining Areas Nos. 8*a* and 6*a*, respectively, enter it.

At the corner of Laurel Hill and Skillman two small trunks enter the West Interceptor.

Design of Trunk Lines from Each Area.

As in our previous report, it has been deemed sufficient for our present purposes to investigate fully the approximate routes, grades, and maximum size of all trunk lines at the point of entrance into the interceptors. In this case, in addition, we have investigated the maximum size of the principal branches of trunk lines where they occur. It has not been deemed advisable to make a more detailed study of these trunks. Such a study would involve the detailed investigation of all existing sewers, information as to which is often meagre or totally lacking. Estimates of capacity of trunk lines are based upon water consumption and ground water flow, as previously described in our Flushing report. Provision for storm water overflows has been made at those points where these proposed lines intercept existing combined sewers, and at two points along Flushing Bay and Creek and one point at head of Newtown Creek. While the sewers have been de-

signed for sanitary and ground water flow only, until the population has been greatly increased, these provisions will suffice for storm water. Assumptions as to the relation between maximum flow and total mean flow for 24 hours have been made as described in our Flushing report. Velocities and discharges have been computed for sewers flowing full, 0.8 full, 0.5 full and 0.2 full. Maximum flows are based upon the sizes necessary at 0.8 full. In the following table the principal items involved in the design of these trunks, including maximum discharge, available slope, maximum diameter, and velocities and discharges at 0.8 and 0.2 full are given:

Design of Trunk Sewers.

Trunk No.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Contributing area, acres.	Maximum discharge, sec. ft.	Slope 1 foot in	Maximum diameter, feet	Sewer 0.8 full.		Sewer 0.2 full.	
								Velocity, sec. ft.	Discharge, sec. ft.	Velocity, sec. ft.	Discharge, sec. ft.
3a	5,000	40.00	81.84	360	6.28	125	1.83	5.75	12.30	3.00	1.08
3a, north.....	7,000	14.00	95.84	180	3.14	500	1.75	2.95	6.15	1.56	0.54
3a, south.....	4,500	15.00	96.84	180	3.14	300	1.67	3.45	6.15	1.80	0.54

104 Design of the Intercepting Sewer.

The design of these sewers is determined by the available slope and by the points of entrance of the various trunk lines. To facilitate reference, the two interceptors and that third line which has been called the "main branch of the East Interceptor," have been sub-divided into sections designated by letters and beginning at the upper end in each case. These sections are described as follows:

The East Interceptor.

Section A, from the upper end of the eastern edge of Area 18, along Myrtle to Cypress, to Himrod, to Covert, to Willoughby, to Onderdonk, to Troutman, to Woodward.

Sections B and C, from the corner of Woodward and Troutman across Linden Hill Cemetery upon the 60-foot contour to Metropolitan, to Nurge, to Flushing, to Grand, to Hull, to Jay and Newtown road, thence following the 40-foot contour to Railway, thence to Maurice, along Maurice to junction with Trunk No. 14 on Thompson.

Section D, a short section on Thompson, from the junction with Maurice to the junction with the present Elmhurst sewer on Broadway, intercepting the latter.

Section E, from Maurice and Broadway, along Broadway to Court, to Suydam, to Junction, to National, to Vine, to Willow, to junction with Trunk No. *5a* on Sycamore.

Section F, from Willow and Sycamore to Central and Willow at the junction with the Main Branch.

Section G, from the junction with the Main Branch along Central to Main, to Myrtle, to junction with Trunk No. *5b* on Flushing and Newtown Turnpike.

Section H, from junction with Trunk No. *5b* practically on the 20-foot contour to shorefront, thence along the shore to junction with Trunks *6b* and 7.

Section I, from the above point, still following the shore line and Shore road, to junction with Trunk *8b* at Ehret avenue and Shore road.

Section J, from Ehret avenue and Shore road along River avenue to junction with outfall sewer on Theodore.

Main Branch of the East Interceptor.

Section A, from upper end on Cooper, along Cooper to Trotting Course Lane at the junction with Trunk *3a*.

Section B, from junction on Trotting Course Lane, following valley line to 40-foot contour, thence following swamp margin to junction with Trunk No. 2 at siphon entrance.

Section C, inverted siphon under Horseshoe Creek from Newtown to Corona.

Section D, from inverted siphon along Westside avenue to South,

to Broad, to Myrtle, to Crown, to Central, to junction with East Interceptor at Central and Willoughby.

105 The West Interceptor.

Section A, from 50-foot contour line on Montgomery on southern edge of Area No. 13*c*., along Montgomery to Waters, to Washington, to Jones, to Laurel Hill Boulevard, to Borden, to Greenpoint and Borden.

Section B, from Greenpoint and Borden, along Greenpoint to Hunters Point, to Honeywell, to Thompson, to Rawson, to Foster, thence diagonally along proposed street to Skillman, skirting the Pennsylvania Railroad yards at Laurel Hill avenue at junction with two small trunks from Area No. 13*a*.

Section C, from last-named junction, still skirting the Pennsylvania Railroad yards, to Webster.

Section D, from Webster and Jackson along Webster to Prospect.

Section E, from Webster and Prospect, along Prospect to Pierce, to Crescent.

Section F, from Pierce and Crescent, along Crescent, to Grand.

Section G, from Crescent and Grand, along Crescent, to Hoyt.

Section H, from Hoyt and Crescent, along Hoyt to Howland, to Ditmars, to Barclay, to Winthrop.

Section I, from Winthrop and Barclay, along Winthrop to Blackwell, to River avenue, to junction with East Interceptor and outfall sewer on Theodore.

The total length, total fall of each section, elevation of invert at upper end of section, area contributing to each section, dimensions, slopes, velocities and discharges at 0.8 and 0.2 full, of the above-described sections of these three interceptors, are given in the following tables:

Section.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Contributing area, acres.	Maximum discharge, sec. ft.	Slope 1 foot in	Maximum diameter, feet.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full. Velocity, sec. ft.	Sewer 0.2 full. Discharge, sec. ft.
Main Branch.											
A	2,200	5.0	41.84	1,172	7.68	440	1.75	3.29	7.68	1.70	0.68

107 Provision for Storm Water.

At all points where the proposed intercepting sewers or trunks intercept existing combined systems of sewerage, present points of final discharge have been retained to serve as stormwater overflows. These points *so* far as our present information goes are as follows: On the West Interceptor overflows are provided at the corner of Hunters Point and Honeywell, and of Nott avenue and Honeywell; at Webster and Prospect; Washington and Prospect; Jamaica and Crescent; Newtown and Crescent; on Hoyt avenue; and Howland and Potter. Storm water overflows into Flushing Creek and Bay are provided on the East Interceptor for the sewage of Elmhurst Section. This matter will be discussed in some detail later in this report.

Provisions for Intercepting Existing Sewers.

On the West Interceptor it has been possible to provide for the greater part of the sewage now flowing into Newtown Creek and the East River from points at higher elevation than that of the interceptor. Such existing sewers as we have knowledge of, which can be provided for, are shown in purple ink on the accompanying map as connected with the proposed interceptor. Sewers on Graham and on Broadway in Long Island City pass under the proposed grade of the interceptor. They are, therefore, not provided for at present. It will be noted that a considerable portion of Long Island City, namely, that part of the East River front which is below the 20-foot contour, which we have called Area 12, is not provided for in this scheme. This section is so completely sewered that special future consideration will have to be given to it. Any plan which contemplates the concentration of the sewage now entering the waterfront from this area must involve a low-level interceptor following the line of Newtown Creek and the East River shore to a point in Astoria whence the sewage will have to be lifted about 25 feet to the West Interceptor. This same provision will apply to those few sewers already noted and doubtless to others of which we have no information which it is not possible to include in the present Interceptor as designed.

Disposition of the Present Elmhurst Sewage and Sewage Disposal Works.

The present plan contemplates the intercepting of the present flow from the Elmhurst Section by the East Interceptor at the corner of Broadway and Maurice avenue. It is believed that for many years to come the present plant at Elmhurst will provide satisfactorily for the disposal of all the sewage which may reach that point; and furthermore that with the advances which we may reasonably expect in the art of sewage disposal, this plant may be able to care for the entire flow from that section of the East Interceptor above Elmhurst. We therefore recommend that until condi-

tions make necessary the further extension of this final plan, the Elmhurst plant be retained to receive all the sewage from such sections of this interceptor as may be connected up from time to time; and we further recommend that studies upon improved methods of disposal, looking particularly toward economy in space and time required for treatment, be continued either at this plant or at some suitable station along the lines that are already developed at the Twenty-sixth Ward Disposal Works, or along new lines which
108 may suggest themselves to us from time to time in consequence of these installations. We urge the importance of continuing on a small scale the study of the special requirements and possibilities in this matter of sewage disposal for Greater New York. The accumulated data of such experiences will be of great value from time to time as such problems are met with.

Purification and Disposal Investigations.

Our more general studies of the ultimate capacity of New York Harbor and its tributary waters to dispose of sewage in an inoffensive manner are still in progress. We are not yet ready to report upon this matter. Before any final decision is arrived at it is desirable to carry our studies to such a point that our opinions shall be based upon a sufficient array of facts to justify them. If it be found that the waters of New York Harbor cannot continue to receive the sewage of the Metropolitan District in its crude form, but that some partial purification of a portion of that sewage at least will eventually be necessary, our plans contemplate such purification in those portions of the city where it can be carried out at a minimum expense. For this reason our studies of the two drainage districts upon which we have already reported have considered a possible necessity of some form of purification, and suitable sites for these works have been selected.

As a minimum requirement we think it necessary to provide for a proper admixture of sewage and water at the point of final discharge; such provision is of much greater importance in the case of these proposed large trunk sewers than it is with the present system of numerous small outlets. With this view in mind, we are investigating the possible methods of securing such admixture before the final discharge. If this can be accomplished it may be possible to so design our outfall works that the sewage will not rise to the surface of the stream, but will remain diffused in the lower strata. Such a result would do away entirely with one serious objection to the discharge of crude sewage into such waters as those we have to deal with, namely, the discoloration of the surface waters and other visible indications of sewage near the point of discharge.

Very respectfully,

W. M. BLACK.
EARLE B. PHELPS.

109 *Special Report on the Flushing Drainage District Submitted to the Board of Estimate and Apportionment April 22, 1910.*

110 CHIEF ENGINEER'S OFFICE,
BOARD OF ESTIMATE AND APPORTIONMENT,
CITY OF NEW YORK, April 11, 1910.

Hon. William J. Gaynor, Mayor, Chairman of the Board of Estimate and Apportionment.

SIR: At the meeting of the Board of Estimate and Apportionment held on November 12, 1909, attention was called to the need of expert advice relative to the location of points at the waterfront which might properly be used for outletting sewers, and acting on the recommendation made at that time the Board retained Colonel William M. Black, U. S. A., to investigate the matter, and with the understanding that his studies should be carried far enough to establish the extent of purification required in sections where the discharge of raw sewage would result in objectionable harbor pollution.

The desired investigation was begun early in January by Colonel Black, who had in the meantime associated with himself Professor Earle B. Phelps, and with the understanding that it would be completed during the coming summer.

After several conferences it was agreed that the field to be covered should include a general study of the districts for which no complete or permanent drainage plans have been devised and so far as required to establish the points of outlet which were practicable, both from the standpoint of sewer design and suitability for such use.

In recognition of the well-founded objections which have been raised to the use in this city of any of the methods now recognized for purification of sewage, it was also agreed that experiments should be made with a process heretofore untried but which had been suggested by Colonel Black in connection with his studies of the Passaic Valley drainage problem and which seemed to be along lines which could be advantageously followed. An experimental plant for determining the merits of this system has been installed in the East New York Purification Works, Borough of Brooklyn, and its operation has just been begun.

Several years ago the construction of a trunk system of sewers for the Ingleside section in the Borough of Queens was authorized by the Board of Estimate and Apportionment, and at a subsequent date it became necessary to abandon the plan for the outlet originally proposed, its unsuitability having been demonstrated. The sewers are now nearly completed, but no provision has yet been made for a permanent outlet; until this is obtained the system cannot be used. For this reason I suggested to Colonel Black that his attention be first given to the district in which these sewers have been built, and under date of March 30 he has submitted the accompanying report which is concurred in by Professor Phelps.

In this report it is demonstrated:

1st. That the drainage of the territory located between the backbone of the island and the East River, and extending from the westerly boundary of the Flushing Creek valley to the westerly boundary of the valley at the head of Little Neck Bay, comprising about 14,900 acres, should be considered as a whole.

111 2d. That the discharge from about 4,500 acres of low land within this area, or about 28 per cent. of the total flow, will have to be pumped, while a gravity outlet can be secured for the remainder of the district.

3d. That if further investigation should establish the feasibility of discharging all of the raw sewage directly into the East River, or if the experimental work now being conducted in the matter of an improved process of purification should give satisfactory results, practically all of the dry weather flow could be outletted about one-half mile west of Whitestone Point, and that in case of failure of the experiments and an establishment of the need of purification the discharge from the greater part of the area could be carried directly to Flushing Bay. In either case, it is believed that the lower areas of College Point, Whitestone, and Bayside can be carried to the Whitestone outlet without purification, it being held that the purification of the flow of the remaining area would permit of the discharge of the raw sewage from this territory, which forms only a small part of the whole.

4th. That if purification is required the site for the works would be located in the vicinity of Whitestone road and Bayside avenue, if the experimental process is satisfactorily developed, and otherwise in the low land north of Flushing.

5th. That the concentration point for the drainage of the low areas will be located in the vicinity of Myrtle avenue and Lawrence street.

6th. That pending the carrying out of the entire project and for a limited time the raw sewage from the Flushing section might be outletted, without purification, into the channel at the head of the bay.

7th. That all sewage should be screened before being outletted.

8th. That for the sections adjoining Flushing Creek, where combined sewers have already been built, provision should be made in the permanent plan for intercepting the dry weather flow and leading it to the outlet now recommended for the entire territory, the surplus flow during storms to be discharged as heretofore.

9th. That, where practicable, future plans for the territory in the vicinity of Flushing Creek should be based on using the separate system for so much of the area affected as is based on the outletting of the surface flow into the creek.

I would recommend that a copy of this report and of the accompanying plan be transmitted to the President of the Borough of Queens for consideration, and that his attention be directed particularly to the fact that the plan is intended to be used only as a general guide in the treatment of the problem and with the understanding that if provision is made for the removal of both storm water and the dry weather flow on the combined plan, as would seem desir-

able, it would doubtless be found practicable and advantageous to make radical changes in certain minor features.

Respectfully,

NELSON P. LEWIS,
Chief Engineer.

112

March 30, 1910.

Mr. Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, New York City.

SIR: In connection with our general studies of the sewage problem of certain portions of Greater New York, we submit herewith the report upon the portion of our work which deals with that part of Queens Borough draining into Flushing Bay and adjacent waters. This section will be known in these studies as the Flushing Drainage Area.

Divisions of the Drainage Area.

For the purpose of this work the above described district has been divided into twelve sections numbered respectively one to twelve, and the section numbered "six" has been further subdivided into three divisions known respectively as *6a, 6b* and *6c*. In the estimation of populations we have allowed either twenty-five or fifty persons per acre depending upon the location of the area in question and the character of the country. Reference to the accompanying map* is invited to make clear the following description of these various drainage areas. The respective areas are marked off in heavy black lines except where such lines coincide with contour, street or stream lines, in which case they are indicated by dotted lines. Contour lines at 20-foot intervals are shown, but these are only approximate.

Maps of detailed topographical surveys were not to be obtained and funds and time for the preparation of such maps were not available. Under these conditions we were obliged to use the general map of the City of New York, prepared by the Topographical Bureau of the Board of Public Improvements, dated January 1, 1900, the topography of which is understood to have been compiled from maps issued by the United States Geological Survey.

Area No. 1—This area is situated along the shore between Whitestone Point and the point at the head of Little Neck Bay. It consists of 1,575 acres, having an estimated future population of 42,250.

Area No. 2 includes that portion of the College Point district which is above the 20-foot contour. It contains 493 acres with an estimated future population of 24,650.

Area No. 3 is a suburban district lying between No. 1 and Flushing Bay, having 1,350 acres, with an estimated future population of 35,600.

Area No. 4 includes that portion of Flushing to the north of Franklin and Sanford avenues which lies above the 20-foot contour.

* Omitted. See general map of drainage Districts of Jamaica, Corona, Flushing and Westchester, p. 148.

It consists of 524 acres, with an estimated future population of 26,200.

Area No. 5 includes that portion of the Ingleside district of Flushing, lying to the south of Franklin and Sanford avenues and extending to the crest line west of the Flushing Cemetery, which is above the 30-foot contour. It consists of 636 acres, with an estimated future population of 31,800.

Area No. 6 is the large suburban district south of Flushing extending on the south to the crest of the entire drainage area and on the west to the limits of the Flushing Creek Valley. It
113 includes a portion of Bayside and a small portion of Flushing. It consists of 5,402 acres, with an estimated future population of 135,050. For the purposes of drainage it is further subdivided into three divisions.

Area No. 7 is a small section lying to the south of Flushing between the Mill Creek Valley above the 60-foot contour and the crest of Area No. 6. It consists of 476 acres, with an estimated future population of 11,900.

Area No. 8 lies on the east side of Flushing Creek Valley, extending to the confluence with Mill Creek. It consists of 893 acres, with an estimated future population of 22,325.

Area No. 9 includes the valley of Mill Creek below the 40-foot contour line on the east side and the 60-foot contour line on the west side, down to Lawrence street. It consists of 905 acres, with an estimated future population of 22,625.

Area No. 10 includes the small district between Flushing and Mill Creeks, and Lawrence and Myrtle avenues, below the 20-foot contour, having an area of 172 acres, with an estimated future population of 8,600.

Area No. 11 includes that portion of College Point between Myrtle and Whitestone avenues and the easterly crest of Area No. 2, which is below the 20-foot contour. It has 763 acres, with an estimated future population of 19,075.

Area No. 12 is on the west side of Flushing Creek Valley and Horse Creek Valley, all below the 20-foot contour. It has 1,734 acres, with an estimated future population of 43,350.

The acreage and population of these twelve areas are tabulated below. The total area of the drainage district is 14,923 acres and the estimated future population, 423,425.

Area.	Acres.	Population.
1	1,575	42,250
2	493	24,650
3	1,350	35,600
4	524	26,200
5	636	31,800
6	5,402	135,050
7	476	11,900
8	893	22,325
9	905	22,625
10	172	8,600
11	763	19,075
12	1,734	43,350
	14,923	423,425

General Scheme of Sewerage for the District.

The project which is here proposed for the collection of the sewage of the entire Flushing drainage area is briefly as follows:

The point of final discharge is located on the East River just to the east of Powells Cove and about twenty-five hundred feet to the west of Whitestone Point. To convey the sewage to this point we
114 have provided two main systems which will be designated respectively as the "high level" and the "low level" intercepting systems. The high level system has three main branches. The first drains Area No. 1, above the 20-foot contour line; the small portion of this area which is below that line, consisting of a narrow strip along the shore, will drain directly to the waterfront. This branch meets the main interceptor at the point of discharge.

The second main branch of the high level system drains Area No. 2 above the 20-foot contour. It enters the main interceptor at the junction of Fourth avenue and Eighteenth street. The main interceptor itself may be considered to start at the point just south of the Flushing Cemetery, which is designated as Point "A." It follows Meadow road in a westerly direction, thence across country to Oak and Parsons, in Ingleside, along Oak to Colden, thence to Franklin, to Lawrence, to Washington, to Prince, to State, to Leavitt, to Whitestone, along Whitestone and Fourth avenue and on a continuation of Fourth avenue to the point of discharge. At a point in Whitestone, near Bayside avenue, suitable land is available for purification works if these be considered necessary. This point will be further discussed.

At the Point "A" previously mentioned the trunks from the Districts 6*c* and 6*b* will enter. The trunk from 6*a* joins the latter at a point shown on the map. The location of each of these trunks is sufficiently well indicated to make detailed description unnecessary. At the corner of Myrtle and Leavitt the force main from the low level interceptor enters this line. A short distance beyond at the proposed site for the sewage disposal works the trunk from Area No. 3 joins this line, and at the points already indicated the main trunks from Areas No. 1 and No. 2 enter. This high level system will therefore drain by gravity Areas Nos. 1 to 7, inclusive, a total area of 10,456 acres on which the estimated future population is 307,450.

The low level interceptor has its low point located at the pumping station near corner of Lawrence and Myrtle avenues in Flushing. To this point a small line draining Area No. 11 is brought. To this point, also, is brought the main trunk from Area No. 12, this trunk crossing Flushing Creek at the foot of Myrtle avenue by means of an inverted syphon. A third line reaches this point by closely following Flushing Creek to its end, draining Area No. 8. This latter line branches at the confluence of Flushing and Mill Creeks, one branch extending to the upper end of the valley of Mill Creek, as shown. The total area tributary to the low level interceptor is therefore made up of Areas Nos. 8 to 12, inclusive, having 4,467 acres with an estimated future population of 115,975. The future discharge of this low level system is therefore seen to be

approximately 28 per cent. of the total discharge from the Flushing drainage area.

From the pumping station to a point already indicated on the high level interceptor there will be a 30-inch cast-iron force main having a total length of approximately 3,000 feet.

Design of Main Trunk Lines from Each Area.

For the purposes of this investigation it has been deemed necessary to determine fully the route, grades and dimensions of the high level interceptor and the routes, points of entrance, and maxi-
115 mum sizes of the trunks of the various areas. It has not been considered advisable to make a more detailed study of these trunk lines. Such a study would involve a full investigation of all existing sewers, information as to which is meagre or altogether lacking. In estimating the maximum capacity of the trunk lines at their point of junction with the interceptor, or with another trunk, a water consumption of 125 gallons per capita per diem has been allowed, based upon the reports of the Chief Engineer of the Board of Estimate and Apportionment. In addition to this strictly sanitary flow an allowance of .003 cubic foot per second per acre has been made for ground water flow. This allowance is based upon the practice of the Borough Engineer of Brooklyn. No provision for storm water has been made further than the placing of storm water overflows at those points at which existing combined systems of sewerage will enter the interceptor. Upon this basis of estimate the flow is found to be .01023 and .01746 cubic feet per second per acre, for populations of twenty-five and fifty per acre respectively. It has further been assumed that of the total flow per 24 hours, half will pass in 8 hours, and upon this assumption the maximum discharge has been estimated. It is believed that this assumption is a conservative one in consideration of the size and length of the trunk sewers. Experience elsewhere has shown that in sewers of this size the ratio of maximum to average flow rarely reaches the value that we have assigned. Velocities and discharges have been computed for sewers flowing full, 0.8 full, 0.5 full and 0.2 full. Estimates of size are based upon the computation at 0.8 full. In the summary which follows it has been deemed sufficient to give this maximum velocity and discharge and the minimum velocity and discharge at 0.2 full. The dimensions, slopes, velocities and discharges of the various trunk lines are given in detail in the following tabulation:

Area No.	Maximum discharge, sec., ft.	Slope 1 foot in	Maximum diameter, feet.	Sewer 0.8 full. Velocity, sec., ft.	Sewer 0.8 full. Discharge, sec., ft.	Sewer 0.2 full. Velocity, sec., ft.	Sewer 0.2 full. Discharge, sec., ft.

116 Design of the Intercepting Sewer.

The design of this sewer from point to point is determined by the available slopes and by the entrance of the various trunk lines. To facilitate reference the sewer will be divided into sections which are described as follows:

Section A—From point A on the map, south of Flushing Cemetery, to the Ingleside inlet, corner of Oak and Parsons.

Section B—From this point to the Flushing inlet on Broadway.

Section C—From the Flushing inlet to the force main junction on Myrtle.

Section D—From this junction to No. 3 inlet at or near the disposal works.

Section E—From No. 3 inlet to the purification works (No. 3 inlet may be at the disposal works, in which case Section E will not have to be considered).

Section F—Purification works to No. 2 inlet.

Section G—No. 2 inlet to No. 1 inlet.

Section H—Outfall sewer.

The dimensions, slopes, velocities and discharges of the high-level interceptor, subdivided into the above-described sections are given in the following table:

Section.	Maximum discharge	Slope 1 foot in	Maximum diameter, feet.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full. Velocity, sec. ft.	Sewer 0.2 full. Discharge, sec. ft.
A	59.2	1,500	5.0	3.45	59.2	1.80	5.13
B	70.3	1,700	5.5	3.45	70.3	1.80	6.10
C	79.5	2,100	6.0	3.22	79.5	1.68	6.90
D	127.0	1,800	7.0	3.80	127.0	1.98	11.10
E and F	141.4	2,100	7.5	3.80	141.4	2.00	12.30
G	150.0	2,000	7.5	3.9	150.0	2.00	13.00
H	167.0	2,000	8.0	4.02	167.0	2.10	14.50

Details of Main Interceptor.

Section.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Elevation of ground, upper end.	Contributing area, acres.
A	6,000	4.0	22.1	33.1	5,878
B	12,000	7.1	18.1	27.6	6,514
C	3,500	1.7	11.0	21.0	7,038
D	3,500	2.0	9.3	20.3	11,505
F	3,000	1.7	7.3	18.8	12,855
G	3,200	1.6	5.6	17.1	13,348
H	1,000	0.5	4.0	16.0	14,923

In order to minimize the expenses to be incurred immediately, in view of the fact that the sewers recommended are of a size suitable to serve a population greatly in excess of that at present found in the drainage area, it is recommended that the interceptors
117 and main trunk lines be constructed first of a less capacity, leaving to the future the installation of a duplicate set on the same lines.

Similarly, it is suggested that as a temporary expedient, while the sewage flow remains at its present volume a temporary outfall could be made into the channel near the head of the bay. This would be less unsanitary than the continuance of discharge through the existing outfalls into Flushing Creek, though not a condition which should be permitted to exist for any prolonged period.

Purification.

We are not prepared at the present time to report upon the degree of purification which we consider necessary in carrying out this drainage project. A site has been selected for purification works if they be found necessary. It was not feasible to determine upon a site nearer the outfall which would intercept all the sewage of the drainage area. It will be noticed that areas No. 1 and No. 2 drain into the interceptor below the purification works. Estimating upon the basis of future populations, these drainage areas will contribute about 15 per cent. of the total discharge. It is our opinion that if purification be necessary at all the remaining 85 per cent. of the discharge can be purified to such a degree that the average purification of the whole will be maintained at a point which is found desirable. In any event and as a minimum measure of purification, we are of the opinion that screening of all the sewage will be necessary. This will involve suitable screening plants on the two trunks indicated and on the main interceptor in addition to any purification which may be decided upon later.

It is recommended that an area of about three acres should be secured at once at the site recommended for the purification works. The value of property in that vicinity is increasing rapidly and should future advances in sewage purification methods make a less area necessary, the excess of land could be sold profitably.

The system, as laid out, is designed for purification by methods other than the form of sprinkling filters now in use. Should it prove necessary to adopt the method of purification by sprinkling filters, the works could be located in the existing marsh land between Flushing and College Point, and would require an area of about forty acres, and the purified effluent discharged into Flushing Bay. All of the flow entering the outfall can readily be brought to this point.

Storm Water Overflows.

The present sewerage system of Flushing is a combined system. This will be intercepted at some point on Broadway and a storm water overflow will be provided and so designed that the maximum

dry weather discharge into the interceptor allowed for Area No. 4 cannot be exceeded in times of storm. This overflow will discharge into Flushing Creek at the foot of Broadway under the bridge. In our opinion this situation is an undesirable one and future construction should as far as practicable be made upon the separate system. We do not, however, advise the complete reconstruction of this Flushing system at present.

Very respectfully,

W. M. BLACK.
EARLE B. PHELPS.

118 *Special Report on the Jamaica Drainage District Submitted to the Board of Estimate and Apportionment, January 12, 1911.*

119 CHIEF ENGINEER'S OFFICE,
BOARD OF ESTIMATE AND APPORTIONMENT,
CITY OF NEW YORK, December 12, 1910.

Hon. William J. Gaynor, Mayor, Chairman of the Board of Estimate and Apportionment:

SIR: Herewith is transmitted the progress report of Colonel William M. Black and Professor Earle B. Phelps, bearing date of November 18, 1910, concerning the investigation made by them relative to the points suitable for use as sewer outlets for the territory comprising the southern slope of the Boroughs of Brooklyn and Queens, extending from the Narrows to the Nassau County line, and also for the section adjoining the north shore in the vicinity of Little Neck Bay, the entire area being designated by them as the Jamaica Drainage District.

The area comprises about 49,000 acres which is estimated to have a total future population of about 1,700,000. Following the method used in the investigation of the Corona and Flushing districts, both of which have been reported upon to the Board, a study has been made of the lines which could be followed for the main sewers of this territory in order to reach the points selected as outlets, and the entire area has been divided into 53 drainage districts, for each of which the trunk lines are indicated, the design being worked out in such a way as to intercept sewers already built and to conform with the plans heretofore adopted in so far as practicable.

Excluding the Little Neck, Coney Island and Rockaway Beach districts, together with the area for which plans have already been prepared with provision for an outlet into the Narrows, the sanitary flow of the entire district now reported upon is to be concentrated at three points, from which it will be discharged into the waters of Jamaica Bay. These concentration points are located, respectively, at Riches Point Meadow, at the site of the Twenty-sixth Ward disposal works, and at a point on the Three-Mile Mill road, near the toe of the upland. The point first referred to is to be used as the outlet for the drainage areas heretofore laid out upon the drainage plan of the City with provision for concentration points at the exist-

ing Sheepshead Bay disposal plant and at the head of Paerdegat Basin, and also for all of the unplanned area west of the Rockaway Parkway.

The Twenty-sixth Ward disposal plant will be used for the collection of the flow from the remaining unplanned area within the limits of the Borough of Brooklyn, together with the flow from the marshland adjoining the Jamaica Bay located west of the Remsen Landing Road, and from all of the portion of the upland within the limits of the Borough of Queens south of the ridge, excepting the area lying east of the Bergen Landing Road and south of the Old Country Road.

The remaining area within the limits of the Borough of Queens, with the exception of the Rockaway Beach and Little Neck sections, is to be outletted from the third concentration point of reference.

Screening and aeration are to be ultimately provided at all of these points, the time of applying the latter and the extent of purification required depending upon the development of each of the areas.

120 Plans have already been adopted providing for the concentration of the sewage from the westerly end of Coney Island at the existing West Twelfth street station, where a chemical purification plant is in use. The investigators recommend that all of the sewage from the island be collected at this point and discharged either into the interceptor which is to extend from the pumping station located at the head of the proposed Bensonhurst Drainage Canal to the Narrows, or that it be discharged about 2,000 feet offshore and south of the westerly end of the island; it is believed that the latter treatment can be resorted to without requiring purification and without causing nuisance.

It is proposed to provide an outlet for the Rockaway section at three points from which the sewage will be discharged about 1,000 feet off-shore at a depth of about 15 feet, no treatment being required other than the removal of the grosser suspended matter, following the method now in use along the New Jersey coast. It is stated that there is "little or no probability of the sewage reaching the beach without such dilution as to make it undistinguishable."

The sewage from the Little Neck Bay section is to be concentrated at a point near the head of the bay, whence it will be forced into tidal waters, after sedimentation, screening and a certain amount of aeration.

The report includes tables giving the elements necessary for the design of the various interceptors and their tributary trunks, together with the pumping capacity required at each of the power plants which will be needed. A plan is also presented showing the boundaries of each of the drainage areas and the route, size and grade of each of the sewers proposed, together with the locations of the pumping stations, concentration points, and points of final outlet.

The study is based entirely on the drainage needs in so far as the sanitary flow is concerned, but provision has been made for storm water overflows at all points where the sanitary trunks intercept existing or authorized combined sewers.

It is understood that the experimental work which has been carried on relative to the aeration process of purification will be made the subject of an independent report, but information is now given indicating the amount of oxygen required in order to accomplish the required degree of purification at each point of outfall. It is understood that owing to a lack of necessary data the map submitted with this report is of a general character and that more precise surveys may establish a need for radical revision of the design in many particulars.

I would suggest that a copy of this report and of the accompanying map be transmitted to the President of the Borough of Brooklyn and to the President of the Borough of Queens, with the recommendation that they be given careful consideration in the preparation of the drainage plans for the areas affected.

Respectfully,

NELSON P. LEWIS,
Chief Engineer.

121 November 18, 1910.

Mr. Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, New York City.

SIR: In connection with our general studies of the sewerage problems of certain portions of Greater New York, we beg to submit herewith a third report which deals with the main drainage problem of that portion of Queens Borough lying south of the ridge with a small area lying adjacent to the head of Little Neck Bay, which was not included in the Flushing District; also the southern portion of the Borough of Brooklyn, lying between the boundary of the Corona District already described and Jamaica Bay and including Coney Island, Bay Ridge and the territory directly tributary to Jamaica Bay. For purposes of convenience and identification we have designated this drainage district "The Jamaica Drainage District," and have further sub-divided it into four sections as follows:

The area south of the ridge including portions of both boroughs; the main portion of the Brooklyn area; the area adjacent to the head of Little Neck Bay, and the whole of Rockaway and Far Rockaway. These subdivisions will be known as the Queens, Brooklyn, Little Neck Bay and Rockaway Sections, respectively. Reference to the accompanying map* marked "The Jamaica Drainage District" will make more clear the discussion which follows.

Divisions of the Drainage District.

For the purposes of this study we have divided the above designated district into fifty-three drainage areas, numbered respectively 1 to 53. In the map the division lines between these areas are indi-

* Omitted. See general map of drainage Districts of Jamaica, Corona, Flushing and Westchester, p. 148.

cated by heavy dotted lines. Contour lines at 20-foot intervals are shown, but these are only approximate, by reason of the lack of detailed topographic surveys and of available time and funds for making such surveys, which has been commented upon in our first report. Our proposed sewer lines are indicated in red and other features are sufficiently described in the legend. Estimates of future populations have been made upon a basis of either twenty-five or fifty persons per acre, depending upon the location of the area in question and the character of the country. Those areas for which a population of fifty per acre has been assumed lie about Jamaica Bay and in the region of the proposed improvements. Owing to the probable character of the future population, laborers about the docks, a water consumption of 100 instead of 125 gallons per day has been allowed. This gives an "equivalent population" of forty per acre with a water consumption of 125 gallons. Our table of estimated future population is based upon this "equivalent population." The populations to be cared for in the Coney Island District and also in the Rockaway District are necessarily treated along somewhat unusual lines. In the case of Coney Island a maximum population of five hundred thousand persons, with an average water consumption of fifteen gallons per capita daily has been assumed, and the sewage has further been assumed to run off in twelve hours. This
122 estimate reduced to our usual basis of calculation is equivalent to a permanent population of seventy persons per acre, with a daily per capita water consumption of 125 gallons. Similar assumptions and calculations for the Rockaway District would give an equivalent permanent population of fifty persons, with a consumption of 125 gallons per capita per day. In other respects our assumptions as to population, water consumption, ground water run-off and ratio of maximum to average discharge are the same as were made in our Flushing report.

The areas will be sufficiently identified by reference to the map* and will be only briefly described:

Areas Nos. 1 to 10, inclusive, lie southeast of the crest line separating the Jamaica from the Flushing District, being numbered consecutively from the northeast corner. Area No. 6 is identical with the present Jamaica District, which already has a system of sewers installed. Area No. 8 is the Richmond Hill District for which sewer designs have been approved.

Areas Nos. 11, 12 and 13 comprise a small belt to the southeast of Areas Nos. 7 to 10.

Areas Nos. 14, 15, 16, 18, 19 and 20 constitute the northeastern corner of Brooklyn Borough, lying north of Rockaway Parkway.

Area No. 17 is entirely swamp land lying between Area No. 13 and Jamaica Bay.

Areas Nos. 21 to 27, inclusive, constitute a second belt lying to the southeast of the belt already described in Queens, extending from the northeastern boundary to Area No. 11, already described.

---

*Omitted. See general map of drainage districts of Jamaica, Corona, Flushing and Westchester, p. 148.

Areas Nos. 28 to 36, inclusive, constitute a third belt lying still lower and extending from the territory described to the Bay.

Area No. 20 is identical with Division "X" of the Sewer Department maps.

Areas Nos. 37 to 41, inclusive, constitute the eastern central portion of Brooklyn Borough, extending from the ridge on the west, which separates this section from the New York Bay drainage area, to Jamaica Bay on the east.

Area No. 42 comprises the whole of Coney Island.

Areas Nos. 43 to 46, inclusive, comprise the remainder of this Borough, which drains naturally to Gravesend Bay.

Area No. 39 is the District "Y."

Area No. 38 is the District "DD."

Area No. 46 is the District "W."

Area No. 45 is the District "Z."

Area No. 44 is the District "EE."

Areas Nos. 37 and 43 are the District "AA."

Area No. 42 includes the District "CC."

Areas Nos. 47 to 50, inclusive, are situated adjacent to and drain into Little Neck Bay.

Areas Nos. 51 to 53, inclusive, include the entire Rockaway and Far Rockaway Districts.

The acreage and future estimated populations of these various drainage areas are tabulated below.

The total area included in the district is 48,916 acres, and the total estimated future population is 1,661,495.

Area No.	Acres.	Assumed future "equivalent population." Per acre.	Total.
1	1,634	25	40,850

Total	48,916		1,961,405

Queens Section.

This section will have two main concentration points, one at the present Twenty-sixth Ward Pumping Station on Second Creek, the other at Third-Mile Mill on Cornell Creek. These concentration points are indicated on the map as "A" and "B," respectively. The sewage will be brought to point "A" by three gravity systems, one draining Areas 17 and 18, the second draining Areas 19 and 20, and the third draining the high-level district included in Areas 1 to 16, inclusive. This interceptor will be known as Interceptor No. 1 and a branch interceptor serving Areas 11, 12 and 13 will be known as Interceptor No. 2.

From point "A" the sewage will be forced through three four-foot cast-iron force mains to a point in Big Fishkill Channel. When the thirty-foot channel is excavated in front of the bulkhead line, the outfall sewers must be discharged into it, as the circulation in Fishkill and Broad Channels will then be markedly lessened, and the points of discharge shown will be in water of less depth. In this as in all cases, the most efficient means possible should be taken to insure diffusion of the sewage effluent in the sea water at the outlet so as to avoid a surface nuisance.

The remaining portions of Queens will drain to concentration point "B" by two main interceptors: Areas 21 to 27, inclusive, are served by high-level interceptors known as Interceptor No. 3; Areas 28 to 34, inclusive, by a low-*level* interceptor known as Interceptor No. 4; and areas No. 35 and No. 36 by a trunk line with two branch lines leading directly to point B.

From point B the sewage will be forced through two four-foot cast-iron force mains to a point in Broad Channel shown on the map.

A discussion of the ability of the waters of Jamaica Bay to dispose successfully of the sewage from these two outlets, without the production of any nuisance, will be deferred to a later section of this report, under the head "Pollution of the Waters and Purification Necessary."

Brooklyn Section.

This section, with the exception of areas adjacent to the Queens boundary line, and which have been included in the Queens section, is already provided with sewer systems or with approved designs. Our proposed plans contemplate certain additions to the existing systems as follows: According to plans already approved, the flow from areas Nos. 43, 44 and 45 will be concentrated at point "E," from which it will be forced by pumping to the final outlet in the Narrows, just above Fort Hamilton. The flow from Coney Island concentrates at "CC," on West Twelfth street and Neptune avenue.

To dispose of the sewage concentrated at this point, we present two alternative projects: First, to lift the flow to a gravity line, leading through a siphon under Gravesend Canal, along Eleventh street and Avenue W to the concentration point "E." The objection to this

plan lies in the pumping of the sewage cityward and discharging it into the Upper Bay, where conditions are not favorable for its reception. The second project contemplates pumping the flow from "CC" seaward, discharging about two thousand feet from shore. To permit this there must be found a point of discharge free from
125 the danger of a return upon the beach. In this project a point has been selected well toward the western end of the Island, and the discharge will be in the path of the current around Nortons Point, so that no return of the sewage to the beach is anticipated.

The easterly section of the Brooklyn District, comprising drainage areas 37 to 41, inclusive, is, with the exception of areas 40 and 41, already provided with approved drainage plans. Areas 38 and 39, shown on the Sewer Department plans as "DD" and "Y," respectively, concentrate at point "N" on Flatlands avenue and Paerdegat Basin. Area 37, being the eastern part of the Sewer Department district "AA" concentrates at a point "P" at Knapp street and Avenue Y. The proposed plan contemplates the concentration of the flow from areas 40 and 41 at a point "M" on Ralph avenue and Avenue T.

A gravity interceptor will collect the sewage from these three points (N, P and M), and conduct it to the proposed disposal works in Riches Point Meadow for treatment. This line will be known as Interceptor No. 5. The sewage concentrated at "M" will be lifted directly to the interceptor at Ralph avenue and Avenue T; the flow of areas 38 and 39 will be lifted to a gravity line leading down Ralph avenue to the interceptor, and the flow concentrated at "P" will be lifted to a gravity line joining the interceptor at Avenue T and Flatbush avenue.

The extent and character of the treatment at the purification works will be discussed in a later section of this report. From these works the discharge will be by means of a 54-inch cast-iron pipe to a point in Rockaway Inlet, as indicated.

Little Neck Bay Section.

This section includes a small area with steep slopes and the design is simple. It is not considered advisable to attempt to carry the sewage from this section into the swifter waters of the Sound. Owing to the shallow character of the Bay and the absence of currents, purification works have been indicated near the point of discharge. The subject of purification will be dealt with in a later section of this report.

Rockaway Section.

The Rockaway section comprises low and flat land. The sewage will be collected at three concentration points with a low level trunk running the entire length of the section. From these points it will be discharged through three outfall sewers extending approximately one thousand feet from shore into water 15 feet deep, where there is little or no probability of the sewage reaching the beach without

such dilution as to make it undistinguishable. The question of the degree of purification necessary in these cases will be discussed in a later section of this report.

Trunk sewers designated in general by the number of the area served will enter these interceptors and concentration points as follows:

Interceptor No. 1.

Trunk No. 1, from the 120-foot contour line on Little Neck road, following Little Neck road and Jericho turnpike to junction with Rocky Hill road.

Trunk No. 2, from near Marvin road, along Clinton avenue to Rocky Hill road, thence to junction point above.

126 Trunk No. 3, from Chestnut, along North Wertland to interceptor on Jericho turnpike.

Trunk No. 4*a* on Hillside avenue, from Vogel to Cornwall to Prospect to Palatina to interceptor on Hempstead and Jamaica Plank road.

Trunk No. 4*b*, from Kilbourn avenue and Old Country road along the latter to interceptor on Plank road.

Trunk No. 5, from Orchard and Hillside along latter to Columbus to interceptor on Fulton.

Trunk No. 6. This trunk is already constructed as a part of the Jamaica system. It runs along Lincoln avenue to the junction with the Hawtree Creek road. An 8-inch branch runs along Van Wyck avenue and Hawtree Creek road to the same junction. At its junction with the road to Bergens Landing its diameter is 2 feet 0 inches; its grade 1 in 750; and its elevation + 15.85. A short branch from this point to the Interceptor on South street is designed. This design, in accordance with the general plan of these studies, is based upon estimated future population, and it is, therefore, larger than the existing trunk, which it serves. The latter will undoubtedly suffice for a considerable period in the future.

Trunk No. 7, from Metropolitan avenue along Gould street to Washington, to Chestnut, to Muh and Atfield avenue, to junction with interceptor on Van Sicklen avenue.

Trunk No. 8. This trunk is already designed as a part of the system of the Richmond Hill section, as shown on Map B-4755, on file in the office of the Chief Engineer, Board of Estimate and Apportionment. It is planned to intercept this trunk at its junction with the interceptor on Metropolis avenue.

Trunk No. 9, from Jamaica avenue to Napier, along the latter to Hatch, to interceptor on Liberty.

Trunk No. 10 (*a*), on Atlantic avenue from Thrall to interceptor on Rockaway Plank road.

Trunk No. 10 (*b*), from Jamaica avenue and Snedeker, along latter to interceptor on Atlantic avenue.

Trunk No. 14, from Hendrix and Belmont, along latter to Fountain to interceptor on Sutter.

Trunk No. 15, from Blake and Cleveland, along latter to New Lots, to Schenck, to interceptor on Wortman.

Trunk No. 16, from Belmont and Stone, along latter to Lott, to New Lots, to Pennsylvania, to Wortman, to interceptor on Hendrix.

Interceptor No. 2.

Trunk No. 11, on Hawtree Creek road, from the 40-foot contour line to Old South road, thence to head of Interceptor No. 2, at Centreville avenue.

Trunk No. 12, from Rockaway Plank road along Centreville avenue to the interceptor on Old South road.

Trunk No. 13 (*a*), from Ocean avenue and Park street, along Park to Woodhaven to Sutter to the cemetery to interceptor on Old South road.

Trunk No. 13 (*b*), from Atlantic avenue and Spruce along Spruce to Liberty to interceptor on Liberty.

127 Concentration Point A.

Trunk No. 17. This trunk is not definitely located, but will run through the central portion of Area No. 17 to Mill road.

Trunk No. 18, along Railroad avenue and Mill road, intercepting No. 17 on the latter.

Trunks Nos. 17-18, from above point of junction around head of Spring Creek Basin to concentration point A.

Trunk No. 19 will drain the southerly portion of Area No. 19 and will run along East One Hundred and Eighth street to Flatlands avenue, siphon under Fresh Creek Basin to discharge into Trunk No. 20, as shown.

Trunk No. 20. This is an intercepting trunk line draining Area No. 20, which is known as "X" on Sewer Department Maps of Brooklyn Borough. Flowing 0.8 full this trunk will amply provide for the future sanitary flow from Areas No. 19 and No. 20.

Interceptor No. 3.

Trunk No. 21 (*a*), from Long Island Railroad along Creed avenue to the upper end of the interceptor at Hollis.

Trunk No. 21 (*b*), from Claremont and Old Country road along the latter to the upper end of interceptor on Hollis.

Trunk No. 22 (*a*), on Old Country road to interceptor on Springfield.

Trunk No. 22 (*b*). This trunk will flow between the 45-foot and 55-foot contour lines through the northeastern section of Area No. 22. It is not definitely located. It will enter the interceptor at Central avenue and Springfield.

Trunk No. 23 (*a*), from a point on Bank avenue, near Springfield road, along Bank to Farmers to interceptor on Central.

Trunk No. 23 (*b*). This trunk is not definitely located, but will run from the northerly boundary of Area No. 23 in a southerly direction to Farmers avenue to the interceptor on Central.

Trunk No. 24, from Long Island Railroad and William street along latter across South street, thence through an unmapped territory to Canton avenue to interceptor on Central.

Trunk No. 25, from Farmers avenue and Merrick along latter to interceptor on Central.

Trunk No. 26 (*a*), from Cumberland and High View along prolongation of latter to interceptor on Anita.

Trunk No. 26 (*b*), from Cumberland and Brown along latter to Norris to interceptor on Meyer.

Trunk No. 27, along Rockaway Plank road, from point near Bergens Landing road to Birch to Central to interceptor on Three Mile Mill.

Interceptor No. 4.

Trunk No. 28, from Long Island Railroad and Rosedale avenue along latter to prolongation of Cherry avenue, thence to upper end of Interceptor No. 4 at Cherry and Old Fosters Meadow road.

Trunk No. 29. This trunk is not definitely located, but will run along the southwestern boundary of the area to the upper end of Interceptor No. 4.

128 Trunk No. 30, along Old Fosters Meadow road from City limits to upper end of Interceptor No. 4.

Trunk No. 31, along Rockaway turnpike, from Hook Creek to Country road, thence to interceptor on Cherry.

Trunk No. 32, along Springfield road, from Clifton avenue to interceptor on Cherry.

Trunk No. 33, along New York avenue, from Long Island Railroad to Nicholas to Rockaway turnpike to Garfield to interceptor on Eighth street, in Idlewild Park.

Trunk No. 34, along Marsh road, from near the waterfront to interceptor on Eighth street, Idlewild Park.

Concentration Point B.

Trunk No. 35. This trunk is not definitely located, but will run in a northeasterly direction through the central portion of Areas Nos. 35 and 36 around head of Bergen Basin to junction with Trunk No. 36.

Trunk No. 36 (*a*) and No. 36 (*b*). These trunks are not definitely located, but will drain the northerly and southerly halves, respectively, of Area No. 36, uniting with Trunk No. 35 at a common junction.

Trunks Nos. 35-36, from the above junction point to Concentration Point B.

Eastern Brooklyn District.

Trunk No. 37, from concentration point P along Avenue Y, Coyle street, Avenue U, Bragg street and Avenue T to interceptor at Flatbush.

Trunks Nos. 38-39, from existing concentration point N along Ralph avenue to interceptor on Avenue T.

Coney Island Section.

Trunk No. 42, from existing concentration point CC under Gravesend Bay Canal along West Eleventh street and Avenue W to existing concentration point E. To be used in case sewage is not discharged into sea directly.

Little Neck Bay Section.

Trunk No. 47, from City line following the valley in the centre of Area No. 47 in a southerly direction, thence still following valley in a northwesterly direction to Broadway, to Pine street, to Orient, to Willow, to Main at Junction with Trunk No. 48.

Trunk No. 48, from point at head of Alley Pond along Alley road, and thence following closely 40-foot contour line in a northwesterly direction to junction with Trunk No. 47 at Willow and Main.

Trunks Nos. 47-48, from the above junction point along Main to Cedar to purification works near head of Little Neck Bay.

Trunk No. 49, from West Alley road, near head of Alley Pond, following 40-foot contour line to junction with Trunk No. 50 on edge of swamp.

Trunk No. 50, from a point to the west of Oakland Lake following 30-foot contour line around Lake to junction with Trunk No. 49.

Trunks Nos. 49-50, from above junction point through meadow under creek to purification works. The kind and degree of purification to be given the sewage at this point will be discussed in a later section of this report.

129 ## Rockaway Section.

The three areas comprising the Rockaway section will be served by three separate systems with independent concentration points and outlets.

Trunks Nos. 51 (*a*) and 51 (*b*). These two trunks run parallel to the shore from the two ends of Area No. 51 to the concentration point X, located as shown.

Trunks Nos. 52 (*a*) and 52 (*b*). These two trunks drain Area No. 52 in a similar manner and concentrate at point Y, as shown.

Trunk No. 53. This trunk runs along the southern boundary of Area No. 53 from near the City limit to the concentration point Z, in the southern corner of the area.

Purification works are provided at each of these concentration points. The kind and degree of purification necessary will be discussed in a later section of this report.

Design of Trunk Lines from Each Area.

As in our previous report, it has been deemed sufficient for our present purposes to investigate fully the approximate routes, grades and maximum size of all trunk lines at the point of entrance into the

interceptor. It has not been deemed advisable to make a more detailed study of these trunks. Such a study would involve the detailed investigation of all existing sewers, information as to which is often meagre or totally lacking. Estimates of capacity of trunk lines are based upon water consumption and ground water flow, as previously described in our Flushing report. Provision for storm-water overflows has been made at those points where these proposed lines intercept existing combined sewers, namely, at the intersection of Trunk No. 6, at Lincoln avenue and Hawtree Creek road; and of Trunk No. 8, on Metropolis avenue; and of Trunk No. 20, previous to its junction with No. 19. The first two overflows will continue in existing or approved sewers to the present Jamaica Disposal Plant; the third by a new overflow to Fresh Creek. While the sewers have been designed for sanitary and ground water flow only, until the population has been greatly increased, these provisions will suffice for storm water. Assumptions as to the relation between maximum flow and total mean flow for 24 hours have been made as described in our Flushing report. Velocities and discharges have been computed for sewers flowing full, 0.8 full, 0.5 full and 0.2 full. Sizes are based upon the normal flow, sewer 0.5 full. In the following table the principal items involved in the design of these trunks, including maximum discharge, available slope, maximum diameter and velocities and discharges at 0.8 and 0.2 full are given:

Trunk No.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Contributing area, acres.	Maximum discharge, sec. ft.	Slope 1 foot in	Maximum diameter, feet.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full. Velocity, sec. ft.	Sewer 0.2 full. Discharge, sec. ft.

133 Design of the Intercepting Sewers.

The design of these sewers is determined by the avilable slope and by the points of entrance of the various trunk lines. Sizes are based upon normal flow, sewers 0.8 full. To facilitate reference, the five interceptors have been subdivided into sections designated by letters and beginning at the upper end in each case. These sections are described as follows:

Interceptor No. 1.

Section A, from Rocky Hill road and North Jericho turnpike along latter to North Wertland avenue.

Section B, from last-named point along Jericho turnpike and Hempstead and Jamaica Plank road to Palatina avenue.

Section C, from last-named point to Old Country road.

Section D, from last-named point along Fulton to Columbus avenue.

Section E, from last-named point along Fulton to Skidmore to Willow to Candace to Larch and South to Wells.

Section F, from last-named point along First street to Van Wyck to Wyoming to Van Sicklen.

Section G, from last-named point along Van Sicklen to Metropolis to Lefferts.

Section H, from last-named point along Metropolis to Hamilton to Liberty to Hatch.

Section I, from last-named point to Rockaway Plank road to Atlantic avenue.

Section J, from last-named point along Atlantic avenue to Elderts lane to Liberty.

Section K, from last-named point along Elderts lane to Glenmore to Railroad avenue to Sutter to Fountain.

Section L, from last-named point along Fountain to Vienna to Atkins to Stanley to Sheppard to Wortman to Schenck.

Section M, from last-named point along Wortman to Hendrix.

Section N, from last-named point to concentration point A.

Section O, outfall force mains from concentration point A to Big Fishkill Channel.

Interceptor No. 2.

Section A, from Centerville avenue and Old South road at junction of Trunks 11 and 12, thence along Old South road to Acacia Cemetery.

Section B, from last-named point around cemetery to Liberty.

Section C, from last-named point along Liberty to junction with Interceptor No. 1 on Elderts lane.

Interceptor No. 3.

Section A, from junction of Trunks 21 (*a*) and 21 (*b*) on Hollis and Springfield along latter to Old Country road.

Section B, from last-named point along Springfield to Central.

Section C, from last-named point along Central to Farmers avenue.

Section D, from last-named point along Central to Canton.

Section E, from last-named point along Central to Merrick road.

134 Section F, from last-named point along Merrick road to Anita, thence to Vine.

Section G, from last-named point along prolongation of Meyer avenue and Claude place to Norris.

Section H, from last-named point along Norris to Campbell to Rockaway turnpike to Rockaway Plank road to Three Mile Mill road to Central avenue.

Section I, from last-named point along Three Mile Mill to concentration point B.

Section J, from concentration point B by pressure force mains to point on Broad Channel.

Interceptor No. 4.

Section A, from junction of Trunks 28, 29 and 30 at Old Fosters Meadow road along Cherry avenue to Country road.

Section B, from last-named point along Cherry avenue and Eighth street to Garfield avenue.

Section C, from last-named point along Eighth street to concentration point B.

Interceptor No. 5.

Section A, from junction with Trunks 38-39 on Ralph avenue along Avenue T to junction with Trunk 37 on Flatbush avenue.

Section B, from Avenue T along Flatbush avenue to a southeasterly direction to purification works on Riches Point Meadow.

Section C, cast-iron force main from purification works to a point in Rockaway Inlet.

Design of the Outfall Sewers.

In addition to the three outfall sections of main interceptors, formerly described, there are five outfall sections contemplated in the proposed plans. Three of these are located on the shore front of the Rockaway District and one in Little Neck Bay, one in Coney Island (alternative project). These will be known as Rockaway Outfall Sewers No. 1, No. 2 and No. 3; Little Neck Bay Outfall Sewer; and Coney Island Outfall Sewer; serving Areas Nos. 51, 52 and 53, the Little Neck Bay District and Area No. 42, respectively.

The total length, total fall of each section, elevation of invert at upper end of section, area contributing to each section, dimensions, slopes, velocities and discharges at 0.8 and 0.2 full, of the above-described sections of these five interceptors, are given in the following tables:

Section.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Contributing area, acres.	Normal discharge, sec. ft.	Slope 1 foot in	Maximum diameter, feet.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full. Velocity, sec. ft.	Sewer 0.2 full. Discharge, sec. ft.

137 Pumping Stations.

These plans contemplate the establishment of eleven pumping stations, the ultimate maximum capacities and approximate locations of which are as follows: The capacities given are net horse power, without reference to efficiency, and refer to total lift between pump-well level and ordinary maximum high tide, in the case of out-fall works, or between the two fixed levels in case of subsidiary pumping stations. This power is also referred to the same maximum run-off for which our sewers are designed, namely, at the rate of half the total daily run-off of sewage in eight hours, plus the normal hourly rate of ground water flow.

In that section which we have described as the Queens Section, the drainage is entirely by gravity to the concentration point "A." At this point a pumping station having a capacity of 951 net horse power will be required.

At concentration point "B" the drainage is likewise collected by gravity systems. At this point a pumping station having a net capacity of 535 horse power will be required.

In the easterly Brooklyn Section five pumping stations have been designed. One located at concentration point "N" will lift the entire drainage from Areas 38 and 39 to gravity trunk designated 38-39. There will be required a capacity of 102 net horse power. A second station is located at concentration point "P," the capacity required being 29 net horse power. At concentration point "M" a pumping station will lift the discharge from Areas 40 and 41 into the gravity line running to the purification works. The capacity of this station will be 24 net horse power. At the purification works a fifth pumping station with a capacity of 258 net horse power will be provided.

In the Western Brooklyn Section the discharge in Trunk 42 will be lifted by a pumping station located at concentration point "CC" into a gravity line running to concentration point "E". A capacity of 15 net horse power will be required. A pumping station at "E" is already designed and it is not discussed in this report. In the alternative Coney Island project, a pumping station for the outfall at "CC" will be required with a capacity of 190 net horse power.

In the Little Neck Bay Section a pumping station located at the purification works will lift the entire discharge of this area and force it through the outfall sewer. A capacity of 48 net horse power will be required.

In the Rockaway Section three small pumping stations, one at each outlet, are provided. That serving Area No. 51 will have a capacity of 49 net horse power, that serving Area No. 52, 34 net horse power, and that serving Area No. 53, 47 net horse power.

Pollution of the Waters and Purification Necessary.

In our previous reports matters relating to water pollution and the purification of sewage were left in abeyance until the completion of our experimental investigation into the condition of the waters of

New York Harbor, and their ultimate capacity to receive sew-
138 age without giving rise to undesirable conditions. This present report deals with the drainage area which is for the most part adjacent to waters which do not constitute a factor in the New York Bay problem. In the location of the seven outfall points which we have selected for this drainage area, therefore, we have given careful attention to the probable effect of such a plan of drainage upon the adjacent waters. The larger part of this entire drainage area, namely,, the Queens and Brooklyn Districts, drains into the waters of Jamaica Bay. Careful investigation of the total amount of water entering this bay from the ocean, during each tidal period, has been made, and by a study of the relative cross sectional areas of the more important channels within the bay and of the tidal prisms tributary to these respective channels, the amount of water available for dilution purposes at each of our three outlets has been approximately estimated. For the purpose of these studies, United States Coast Survey Chart No. 542 and the records of the United States Engineer Office were used in estimating the effective dilution. The amount of partially polluted water remaining in each channel at the beginning of the flood was determined and was added to the total discharge during the next tidal period. This process of summation was continued for a series of tides until the residual correction became so small as to be negligible. In this manner the ultimate dilution of sewage discharged at each of the three outfalls and the ultimate dilution of the entire discharge with reference to the entire tidal flow in and out of Jamaica Bay was determined. The sewage discharged into Rockaway Inlet from Riches Point Meadow, if considered alone, would have an ultimate dilution, determined as indicated, of one part in 2,670, but when considered together with the discharges into other portions of the bay, the ultimate dilution is one in 209. The discharge from concentration point "A" into the Big Fishkill Channel will have a similar ultimate dilution of one part in 75. Sewage discharged from concentration point "B" into Broad Channel will have a similar ultimate dilution of one part in 95. The final dilution of the combined flow from these three discharges into the waters of Rockaway Inlet will be one part in 209, as stated above. These figures are based upon an assumption of thorough diffusion, and at such times as slack water the percentage of pollution will be much greater.

In the course of our experiments, which have been carried on during the past eight months, we have determined, among other things, the amount of oxygen which the sewage of Brooklyn as it now runs to the East New York Pumping Station will absorb from aerated water. The full details of these experiments will be reported upon in a special report. For our present purposes it may be stated that the oxidizability of the sewage in question, or its capacity for absorbing oxygen from the water with which it is mixed varies greatly during the season, being greatest in the summer time and least in the winter. One million gallons of the sewage, if diluted in 100 million gallons of sea water, will, in the course of twelve hours, ab-

sorb from the water about 1,950 pounds of oxygen, under conditions which exist during three months in the summer. During the remainder of the year the absorption averages about 500 pounds per million gallons. Obviously it is necessary to provide for the extreme conditions of summer. Under these same conditions the water of the outer bay may be assumed to have a temperature of about 17 degrees C., and a corresponding oxygen content of
139 66.8 pounds per million gallons. In this case it will be safe to allow a reduction of this oxygen to at least 75 per cent of the full saturation value, giving us 25 per cent, or 16.7 pounds of oxygen per million gallons of water available for purposes of oxidation; a reduction in the oxygen value to less than 50 per cent of saturation is almost sure to result in a nuisance, and as we are dealing here with average conditions, it is believed wise to base our calculations upon a reduction to about 75 per cent, thus allowing a margin of safety for fluctuating conditions of sewage flow and tide. Our fundamental data under extreme summer conditions are, therefore:

(1) One million gallons of crude sewage will absorb 1,950 pounds of oxygen in 12 hours, or one tidal period.

(2) One million gallons of sea water contain 16.7 pounds of oxygen which is available for purposes of oxidation.

With this data it is a simple matter to determine the limiting dilution of 1 in 117, above which it is not safe to go.

One other possible source of oxygen suggests itself, namely, absorption from the atmosphere. This phenomenon of absorption or reaeration undoubtedly exists, but a careful study of its quantitative aspects has convinced us that it has little practical value under the conditions with which we have to deal.

It is obvious, therefore, that with the full development of this drainage system some means will have to be utilized to reduce the oxidizability of the sewage before discharge.

The oxidizability referred to above was obtained from the crude sewage as it is now received at the pumping station. There can be little doubt but that some comparatively simple screening will reduce the figure somewhat, so that ultimate dilutions of 1 in 100 may be possible.

For a further reduction in oxidizability some form of purification will be found necessary. Our experiments have proceeded far enough to enable us to state at this time that by a simple and cheap process of aeration the oxygen requirements of the sewage can be reduced at least one-half, and probably, under summer conditions, two-thirds. In other words, this sewage which will now absorb 1,950 pounds of oxygen per million gallons in 12 hours, can by some such process as we shall fully describe later, be so altered that it will absorb not more than 975, and possibly not over 650 pounds. This will make dilution of 1 in 50, or less, permissible, and obviate entirely the necessity for further purification of sewage by filters.

We are prepared to recommend, therefore, that at Riches Point Meadow concentration point, and at both concentration points "A" and "B," provision be made for screening and aerating the sewage

before discharge. Details of the aeration process will be given in a subsequent report. This treatment will probably not be necessary until the proposed drainage system has been developed to at least one-half of its ultimate capacity. After that time it will be necessary to employ the aeration process only during certain of the summer months, and at ultimate development such employment will probably not exceed four months of the year. These facts have an important bearing on the consideration of the ultimate cost of treatment.

140 The discharge into Little Neck Bay is necessarily into shoal water near the head of a land-locked bay in which practically the only circulation is that due to tidal flow. It is therefore impossible to make any accurate calculations of the dilution factor, but purification will evidently be required. We recommend at the start effective fine screening, a short period of sedimentation, and forced aeration. Our recommendation of the latter process is based upon experimental work which we have conducted during the summer at Brooklyn and at Boston. This work is not yet completed, but has gone far enough to enable us to state that in situations similar to the one under discussion an important reduction in the putrescibility of the sewage can be obtained in this manner and at reasonable costs.

The three outlets along the shore front of the Rockaway Section will each be carried about 1,000 feet off shore into water having a mean depth of 15 feet. Experience elsewhere, notably at Asbury Park and Ocean Grove, has indicated that with suitable provision for the removal of the grosser suspended matter, such a method of disposal may be used without any resulting nuisance. We recommend disposal work at these points, consisting of screening and a short period of detention in hydrolytic tanks, so designed as to clarify the sewage and give a maximum of liquefying action with a minimum of anaerobic putrefaction.

Very respectfully,

W. M. BLACK.
EARLE B. PHELPS.

(Here follows map marked page 141, Complainants' Exhibit No. 136.)

142 *Special Report on the Richmond Drainage District.*

Submitted to the Board of Estimate and Apportionment March 9, 1911.

143 CHIEF ENGINEER'S OFFICE,
BOARD OF ESTIMATE AND APPORTIONMENT,
CITY OF NEW YORK, March 4, 1911.

Hon. William J. Gaynor, Mayor, Chairman of the Board of Estimate and Apportionment:

SIR: Herewith is transmitted the report of Colonel William M. Black, U. S. A., and Professor Earle B. Phelps, bearing date of February 15, 1911, in the matter of the locations which might properly be selected for the discharge of sewage from the entire Borough of Richmond.

This report has been prepared pursuant to the instructions given by the Board in 1909, under which Colonel Black was requested to advise concerning the method which, in his judgment, might properly be adopted in order to most advantageously use the harbor waters for the removal of sewage, and has been prepared along the same lines as were followed in investigating the Corona, Flushing, and Jamaica districts of the Borough of Queens, in each of which sections it was found necessary to outline a general plan for the drainage of the entire area affected in order to establish the practicability of using the points selected for outlet.

The report now submitted completes the investigation in so far as it relates to the portions of the City for which no complete drainage plan has yet been prepared.

The investigation was also made to include a study of the circulation of fresh and polluted water in the harbor, with a view of determining the amount of sewage which could properly be admitted in various sections, together with the results of experimental work concerning a new process of purification which it was believed might be employed with advantage. The results of the latter investigation are contained in another communication which will be made the subject of a separate report, this completing the entire work originally contemplated.

In this report it is pointed out that about 63 per cent. of the entire area of the Borough of Richmond is located on the northwesterly side of the backbone of the island and drains naturally into the Arthur Kill and the Kill von Kull, and that of the 36 miles of coast line about one-half borders upon the kills, neither of which can be considered as available for the discharge of crude sewage. It is also pointed out that the five miles of coast line bordering the upper bay are similarly unavailable for such use owing to the pollution to which they are already subjected, and that of the remaining thirteen miles having frontage upon the lower bay a considerable portion is unavailable for the discharge of sewage owing in part to the shallow

depth, and in part to the tidal circulation which would result in the return of discharged sewage to the bathing beaches. These conditions leave only the upper portion of the lower bay in the vicinity of the Narrows and the southerly portion of the island as the only sections along the coast line suited for the use under consideration unless purification is resorted to. The plan which has been outlined is intended to meet these conditions in so far as practicable and provides for the collection and discharge of sewage at seven points.

144 Two of these points are located in the vicinity of Fort Wadsworth, here outletting into the deep waters of the Narrows. At these two points there will be concentrated more than one-half of the total sanitary flow for the Borough, this being accomplished by bringing a portion of the sewage from the westerly water-shed southwardly through the gap at Richmond, thence returning along the easterly slope of the island.

The five remaining points are located respectively at Great Kills, Seguine's Point and Red Bank on the southerly side of the island, and at Lake's Island and Bloomfield on the Arthur Kill. At the last two mentioned points purification by sedimentation and forced aeration will be required.

It has been assumed that the island will have a population representing a density of about 25 persons per acre and that the dry weather flow will be equivalent to a water consumption of 125 gallons per capita per day, of which one-half would be discharged into the sewers in eight hours. In determining the size of sewers for the sanitary flow an allowance has been made for a seepage of ground water at a uniform rate of 0.003 cubic feet per second per acre. It has been assumed that the flow in the sewers will have a velocity of three feet per second, and that a minimum of six feet of cover will be provided.

In the studies no provision has been made for the removal of the storm flow, it being understood that this study was in no way connected with the investigation desired by the Board.

Owing to the low elevation of many of the areas affected it has been deemed necessary to make provision for eleven pumping stations at which the sewage would be elevated through heights varying from 6 feet upwards to 42 feet, requiring an aggregate of 525 horse-power. Provision is also made for six force mains having an aggregate length of about 18,900 feet.

The report includes tables giving the essential elements of the system as planned, which is also shown upon a general map which accompanies the report.

It is understood that owing in part to the absence of data on which a complete plan could be prepared, and in part to the fact that this investigation was intended to be limited simply to such work as was involved in establishing the practicability of carrying the drainage to the points selected for outlet that the plan is not offered as of other than of a suggestive character and that a more or less radical revision may be necessary in many particulars.

I would recommend that a copy of this report and of the accompanying map be transmitted to the President of the Borough of

Richmond with the suggestion that he be asked to give them careful consideration in the preparation of the drainage plans for this district.

Respectfully,

NELSON P. LEWIS,
Chief Engineer.

145 February 15, 1911.

Mr. Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, New York City, New York:

SIR: In connection with our general studies of the sewerage problem of certain portions of Greater New York, we submit herewith a report upon that portion of our work which deals with the Borough of Richmond, and which, in accordance with our previous practice, we will term "The Richmond Drainage District."

Physical Features.

Physically, the Borough of Richmond, or Staten Island, is not well suited for an economical design of a comprehensive drainage system. Although presenting bold slopes and favorable grades in many cases, in others, flat, marshy tracts render the collection of sewage by gravity extremely difficult. Again, the ridges and hills which produce the favorable slopes in some places, offer a most effective barrier to the outlet of the sewage when once collected, except by long detours and consequent loss of elevation, or by still more expensive processes of tunneling.

The island drains naturally in two directions; to the east, or towards the Lower Bay, where tidal circulation is excellent, the water is constantly renewed by influx from the unpolluted supply of the Atlantic Ocean, and the capacity for sewage reduction is almost unlimited; and to the west, or towards the Arthur Kill, where tidal circulation is poor, the water merely rising and falling without greatly changing on each tide, and where it is reported that in parts pollution from the various New Jersey rivers has already passed the stage of a nuisance.

The divide between these two watersheds consists of a pronounced ridge, running the entire length of and forming the backbone of the island. At the north end this ridge rises abruptly to a height of 200 feet and over, continuing south with steep slopes on either side, and increasing gradually in elevation to over 400 feet at a distance of about four miles from the upper end. Two miles farther south the ridge drops suddenly to the lowest point of its entire length, and rises again, but more gradually, forming a gap at an elevation of about 50 feet. From this gap, which plays an important part in the design hereinafter proposed, the ridge continues irregularly to the southern end of the island, averaging only about 100 feet in height, and nowhere rising above 150 feet.

The total length of the island is about thirteen miles, and its greatest width about eight miles. The area is over 57 square miles,

or 36,623 acres, of which 13,584 acres, or 37 per cent., lie in the eastern watershed, and 23,039 acres, or 63 per cent., in the western watershed, which drains naturally into the already polluted kills.

146 In the upper part of the island, and bordering upon the Arthur Kill, are extensive swamp areas, aggregating about 6,461 acres below the 10-foot contour.

The length of coast line is 36 miles, of which 18 miles, or 50 per cent., border upon the kills, and are not available for the discharge of untreated sewage, 5 miles upon the Upper Bay, which is already greatly burdened by the sewage from the East and Hudson Rivers and the Kill von Kull, and will soon feel the effects of the New Passaic Valley outlet, which leaves barely 13 miles, or 36 per cent. of the total perimeter, bordering upon the Lower Bay, where raw sewage may be safely discharged. Again, certain points only of this coast are available for discharge, as the water is shoal and prevents good tidal circulation in a number of places. At the Narrows, discharge is safe if carried out to deep water in the channel; below this, at the beaches, everything discharged returns upon the shore, so that no outfalls are permissible in this vicinity. The lower half of this coast, however, embracing the stretch between Great Kills and the southern extremity of the island, is shown by the United States Coast Survey charts to have a channel parallel to the shore, into which sewage may be discharged with a reasonable certainty of its being carried away by the tidal currents.

Division Into Drainage Areas.*

The island is divided into nine main divisions, lettered A to I, inclusive, as explained in the succeeding paragraphs, and each division is further divided into several drainage areas, numbered 1 to 85, inclusive, for the entire island. The locations of these areas are as follows:

Division A, Areas 1-9.

This comprises the area lying on the western slope of the ridge and tributary to the Kill von Kull, extending westward to the low land bordering upon the Arthur Kill.

Area 1 comprises Districts 17 (*a*), 18 (*a*), and 19 (*a*) of the Sewer Department.

Area 2 comprises the valley extending inland from Port Richmond.

Area 3 is composed of that section of the north shore extending from Snug Harbor westward to Port Richmond.

NOTE.—Areas 1-3 require a low-level system, the flow from which will be concentrated at the Shore road (Richmond terrace) and Columbia street, and pumped through a force-main along the latter to the gravity Interceptor at Post avenue.

Area 4 is a large tract lying upon the slope of the ridge, and extending from the crest down to the 50-foot contour.

* See map of Richmond Drainage District following p. 182.

Areas 5 and 6 occupy the head of the valley of Clove Brook, extending to the crest of the ridge.

Area 7 occupies the remaining portion of the valley around Richmond Lake and lying above the 40-foot contour.

Area 8 lies between Area 3 on the north and Area 6 on the south.

Area 9 lies at the junction of the line of the ridge with the shore.

Division B, Areas 10-17.

This comprises the area lying on the eastern slope of the ridge, above the Narrows, and tributary to the Upper Bay.

147 Areas 10, 11 and 12, occupy the extreme northeast corner of the island, 11 and 12 comprising Districts 1 (*a*) and 1 (D), respectively, of the Sewer Department.

Areas 13, 14 and 15 occupy the valley extending from Tompkinsville inland to the Fingerboard road.

Area 16 borders upon the Upper Bay, just above the Narrows.

Area 17 comprises the western shore of the Narrows, and includes the military reservation of Fort Wadsworth, which may at some future date connect with the sewerage system of the borough.

Division C, Areas 18-33.

This comprises the area lying on the western slope of the ridge, above the 50-foot contour, between Willow Brook on the north and Huguenot avenue on the south.

Areas 18, 19, 20 and 21 lie upon the western slope of the ridge, above the Gap, and in the order named from Willow Brook to Richmond Creek.

Areas 22 and 23 occupy the valley just west of the ridge and extending north from the Gap.

Areas 24 to 33 lie in an irregular semi-circle between the summit of the ridge and the low land bordering upon the Fresh Kills.

Area 24 lies at the western extremity of this semi-circle, near the Arthur Kill, and Area 33 at the eastern end, just south of the Gap.

Division D, Areas 34-46.

This comprises that area lying on the eastern slopes of the ridge, above the 40-foot contour, between the Narrows on the north and Great Kills on the south, including the low land back of South Beach.

Areas 34 and 35 occupy the eastern slope of the ridge, adjacent to the Gap, and between the summit and the low land around Great Kills.

Area 36 occupies the valley east of the ridge and north of the Gap.

Area 37 includes the village of New Dorp, lying at the mouth of the valley comprising Area 36.

Areas 38 and 39 lie upon the eastern slope of the ridge, back of Grant City.

Areas 40, 41 and 42 comprise the low land bordering upon the Lower Bay and extending from South Beach on the north to Elm Tree Beacon on the south.

Areas 43, 44, 45 and 46 lie, in the order named, upon the southern slope of the spur ridge extending from the main ridge to the Narrows.

Division E, Areas 47-51.

Areas 47 and 48 occupy the low land composing the western shore of Great Kills Bay.

Area 49 occupies the low ground extending from the head of Great Kills Bay back to the 50-foot contour.

Area 50 includes the low land north of Great Kills Bay and bordering upon the Lower Bay.

Area 51 constitutes the small peninsula which forms the eastern shore of Great Kills Bay.

148 Division F, Areas 52-58.

Areas 52, 53, 54 and 55 extend, in the order named, along the shore of the Lower Bay, from Great Kills on the north to Seguine's Point on the south.

Areas 56 and 57 occupy the head, and Area 58 the mouth, of the valley of Lemon Creek, which extends inland from the head of Princes Bay.

Division G, Areas 59-68.

This comprises the entire southern end of the island.

Areas 59, 60, 61, and 62 lie upon the shore of Arthur Kill, extending south from Smoking Point to Mill Creek.

Area 63 lies between the areas bordering upon Arthur Kill, and the summit of the ridge, north of Mill Creek.

Area 64 occupies the low land bordering upon the Arthur Kill, south of Mill Creek.

Area 65 lies south of Mill Creek, between the summit of the ridge and Area 64.

Area 66 lies upon the shore of Princes Bay.

Area 67 occupies the southern extremity of the island.

Area 68 lies upon the eastern slope of the ridge, about midway between Princes Bay and the southern extremity of the island.

Division H, Areas 69-79.

This comprises the low area tributary to the Fresh Kills and Arthur Kill.

Area 69 lies upon either side of Richmond Creek, just west of the Gap.

Areas 70, 71 and 73 occupy the south bank of Richmond Creek, extending, in the order named, from Area 69 towards the Arthur

Kill, and Area 72 lies between Area 71 and the summit of the ridge.

Area 74 lies upon the shore of the Arthur Kill, south of Fresh Kills.

Areas 75, 76 and 77 occupy the low ground east of Fresh Kills Creek, lying below the 50-foot contour, extending, in the order named, from the head of the creek to the fork of Fresh Kills.

Area 78 lies on the coast of Arthur Kill, north of Fresh Kills.

Area 79 comprises Lakes Island, at the mouth of Fresh Kills.

Division I, Areas 80-85.

Areas 80 and 81 occupy the coast of Arthur Kill, opposite the mouth of the Rahway River, New Jersey, and Pralls Island, respectively.

Areas 82 and 83 occupy the valley of Old Place Creek.

Area 84 occupies the extreme northwestern corner of the island, at the opening of the Arthur Kill into Newark Bay.

Area 85 lies upon the shore of Arthur Kill, between the mouth of Old Place Creek on the north, and Pralls Island on the south.

The acreage and estimated future populations of these 85 drainage areas are tabulated below. The total area of the district is seen to be 36,623 acres and the total estimated future population 915,575.

General Scheme of Sewerage for the District.

The proposed design takes advantage of the most favorable physical features, and attempts to reduce to a minimum the cost of overcoming the difficulties.

Items which add greatly to the expense of a sewer system are: pumping, purification, detours involving great length of line, and tunneling. In order to concentrate at points allowing safe discharge, a certain amount of pumping is necessary, but this item has been kept as low as possible consistent with the avoidance of outfalls where purification would be required, and no lifts are here contemplated on the main lines, except where a force-main outfall must be installed, so that, generally, the amounts lifted, as well as the lifts themselves, are small, and may be served by automatic pumping stations.

Where pumping to a point of safe discharge would cost in excess of the cost of partial purification, small works are contemplated to purify to such extent as will render discharge into the Arthur
151 Kill unobjectionable. Only such degree of treatment is required as will produce an effluent of sufficient stability to delay putrefaction until the larger reservoir of the Lower Bay is reached.

At the main points of discharge, at the Narrows and in the Lower Bay, no purification is considered necessary.

Some long detours will have to be made, to secure favorable grades and to avoid the necessity of tunneling, which expedient will not be necessary in this design. The detours which are required to secure an outlet at the Gap will be less expensive than a tunnel through the ridge at any other point, as the distance between low ground on either side is considerable except at the Gap.

Divisions A and B, Areas 1-17.

The proposed design is as follows:

The area west of the ridge and tributary to the Kill von Kull, back to the low land bordering upon the Arthur Kill, is drained by a gravity interceptor, No. 1, along the north shore, the lower ground being served by a low-level system, whose flow is lifted by pumping to the level of Interceptor I. This interceptor encircles the northern point of the island, and serves also that area east of the ridge and above the Narrows which is tributary to the Upper Bay. The Outfall is just above Quarantine, at the foot of Pennsylvania avenue. The area tributary to this system is 8,013 acres, and the estimated maximum discharge at the outfall is 81.95 second-feet.

Divisions C and D, Areas 18-46.

The area lying on the western slope of the ridge, above the fifty-foot contour, and extending from about Willow Brook on the north to Huguenot avenue on the south, is served by two gravity inter-

ceptors, Nos. II and III, which unite at the Gap. Interceptor II serves the area north of the junction, and Interceptor III that to the south. After the junction, the interceptor, now known as No. IV, crosses the ridge at the Gap and serves that portion of the eastern slope between Great Kills and the Narrows which lies above about the forty-foot contour. The low-lying area back of and including South Beach is also served by this system, the flow being lifted through a force-main to Interceptor IV, in order to prevent the fouling of the beaches which would result were the outfall placed in this vicinity. The final discharge is located just below the Narrows, in deep water off shore.

The area tributary to this system is 10,574 acres, and the estimated maximum flow at the outfall is 108.18 second-feet.

Division E, Areas 47-51.

The low-lying area in the vicinity of Great Kills Bay is concentrated by gravity at a point near the head of the Bay, and pumped out to sea.

The tributary area is 1,992 acres, and the discharge 20.39 second-feet.

Division F, Areas 52-58.

The area on the eastern slopes of the ridge, lying between Great Kills on the north and Princes Bay on the south, most of which has a good elevation, is drained by Interceptor V to a concentration point at Seguine's Point, near the head of Princes Bay, and pumped Seaward.

The tributary area is 3,337 acres, and the discharge 34.14 second-feet.

152 Division G, Areas 59-68.

The area on the western slopes of the ridge, lying between Smoking Point on the north and the southern extremity of the island, is concentrated by Interceptor VI, with one relay lift for that portion north of Kreischerville, at a pumping station on Mill Creek, whence it is pumped through a force-main to a continuation of the gravity interceptor at the summit of the ridge. From this point the discharge is by gravity into the deep water off shore.

The area tributary to the gravity system of this division is 2,624 acres, and the maximum discharge is 26.84 second-feet.

The low level portion of this Division consists of the area lying on the eastern slope of the ridge, between Princes Bay and the southern end of the island, whose flow is collected by gravity at Red Bank, and lifted to the gravity outfall, by pumping.

The area tributary to this low level system is 1,197 acres, and the discharge is 12.25 second-feet.

The total area of Division G is 3,821 acres, and the discharge is 39.09 second-feet.

Division H, Areas 69-79.

The low, marshy area adjacent to the Fresh Kills, and tributary to the Arthur Kill, is served by two interceptors, Nos. VII and VIII, draining, with one relay lift in each, the areas south and north, respectively, of Fresh Kills and Richmond Creek. Both interceptors concentrate at the same point on Lakes Island, at the mouth of Fresh Kills, where the sewage will be purified sufficiently to permit its discharge into Arthur Kill without nuisance.

The tributary area is 4,962 acres, the discharge 50.75 second-feet.

Division I, Areas 80-85.

The flow from the low area occupying the northwestern corner of the island, and tributary to the Arthur Kill, will be concentrated by a gravity interceptor, No. IX, at a point on the shore of the Arthur Kill, north of Pralls Island, where it will be partially purified and finally discharged into Arthur Kill.

The tributary area is 3,924 acres, and the discharge 40.13 second-feet.

Trunk sewers are designated in general by the number of the area served. Their locations are as given in the following summary a study of which will be facilitated by reference to the accompanying map. The division lines between areas are indicated by heavy dotted lines, the sewers in solid red lines. Other devices used are sufficiently explained in the legend. Contours are at 20-foot intervals.

Division A.

1. From 1,000 feet west of South avenue, east along Shore road (Richmond terrace), to junction with Trunk 2 at Lafayette avenue.

2. From near Richmond turnpike, north, nearly parallel to Port Richmond road and Richmond avenue, to junction with Trunk 1 at Shore road (Richmond terrace).

1-2. Along Shore road (Richmond terrace), from Lafayette avenue to Columbia Street Pumping Station.

153 3. From Bard avenue, west along Richmond terrace to Columbia Street Pumping Station.

1-2-3. Columbia Street Force-main. From Columbia Street Pumping Station, at Richmond terrace, south along Columbia street to Interceptor I. at Post avenue.

4. From near Ocean Terrace road, at summit of the ridge, west down valley of stream to about 50-foot contour; thence along latter to junction with Columbia Street Force-Main at Columbia street and Post avenue.

5. From near summit of ridge, north along valley of stream to junction with Trunk 6 at Schœnian Pond.

5-6. From Junction of Trunks 5 and 6, north along valley of Clove Brook to Richmond Lake.

7. No trunk has been designed for Area 7, the flow from which will be considered as entering Trunk 5-6 at Richmond Lake.

5-6-7. From Richmond Lake, north along valley of Clove Brook to Interceptor I at Post avenue and Columbia street.

8. From near summit of ridge, northwest along valley of stream, to Castleton avenue, along Castleton avenue, Rement avenue to Interceptor I at Henderson avenue.

9. From summit of ridge, north along Lafayette avenue to Interceptor I. at Richmond terrace.

Division B.

10. From near summit of ridge, north along Richmond turnpike and Jersey street to Interceptor I. at Richmond terrace.

11. No trunk has been designed for Area 11, as this area is already sewered, and its trunk will be intercepted at Church street and Richmond terrace.

12. No trunk has been designed for Area 12, as this area is already sewered, and its trunk will be intercepted at Arietta street and Central avenue.

13. From junction of Fingerboard and Richmond roads, north along valley of stream to De Kalb avenue.

14. No trunk has been designed for Area 14, the flow from which will be considered as entering Trunk 13 at De Kalb avenue.

13-14. From De Kalb avenue, north along Danube avenue, Simonson place and Targee street to Laurel avenue.

15. No trunk has been designed for Area 15, the flow from which will be considered as entering Trunk 13-14 at Targee street and Laurel avenue.

13-14-15. From Targee street, along Laurel avenue, Gordon, Broad and Canal streets to Interceptor I. at Riker street.

16. From Grasmere Lake, north and east to Interceptor I. on Willow avenue.

17. From high ground back of Fort Wadsworth, east and north along Fingerboard road and New York avenue to junction with Interceptor I. at Pennsylvania avenue.

Division C.

18. From about 300-foot contour, on Manor road, west down valley of Willow Brook to near Willow Brook road; thence southwest to Interceptor II. at Rockland avenue, on 50-foot contour.

154 19. From about 220-foot contour, at Manor road, west down valley of Springville Creek to junction with Trunk 18 at 50-foot contour.

20. From about 140-foot contour, near Forest Hill avenue, west and south to Interceptor II, south of Richmond Hill road.

21. From about 130-foot contour, near crest of small ridge, south along valley of stream to Interceptor II.

22. From 300-foot contour, near Egbert avenue, south down valley of Richmond Creek to 100-foot contour on Saw Mill road.

23. No trunk has been designed for Area 23, the flow from which will be considered as entering Trunk 22 at the 100-foot contour on Saw Mill road.

22-23. From 100-foot contour, on Saw Mill road, south along valley of Richmond Creek, to Interceptor II. at Richmond.

24. From about 100-foot contour, near Huguenot avenue, north and east to junction with Trunk 25 at 50-foot contour, north of Washington avenue.

25. From 120-feot contour, along Washington avenue and valley of small stream to Interceptor III. at 50-foot contour.

26. From near Fresh Kills road, south along Greenridge avenue to Interceptor III.

27. From about 140-foot contour, near Huguenot avenue, east and north along valley of small stream to junction with Trunk 27-28 at Washington avenue.

28. No trunk has been designed for Area 28, the flow which will be considered as entering Trunk 27 at Washington avenue.

27-28. From junction of Trunks 27 and 28, east and north to Interceptor III.

29. From 80-foot contour, Woods of Arden, northeast, parallel to railroad to Wilson avenue; thence west along valley of stream to junction with Trunk 30 at about 50-foot contour.

30. From 60-foot contour, at Gifford's, south to Trunk 29.

29-30. From junction of Trunks 29 and 30, along valley of small stream to Interceptor III.

31. From 60-foot contour, north of Gifford's lane, west to Interceptor III.

32. From 80-foot contour, north along valley of small stream to Interceptor III.

33. From near summit of ridge, south of Gap, to Interceptor IV. at Gap.

Division D.

34. From Great Kills north, parallel to railroad, to junction with Trunk 35 at Clark avenue.

35. From 80-foot contour, east on Clark avenue to Trunk 34.

34-35. From junction of Trunks 34 and 35, north, parallel to railroad, to Interceptor IV. at Amboy road.

36. From 340-foot contour, on Todt Hill road, south along valley of creek to junction with Trunk 37 at Sixth street and Elm avenue, New Dorp.

155 37. From 140-foot contour, near New Dorp Beacon, east and south down valley of stream, along Grand avenue, Richmond road, Amboy road, Ocean avenue and Sixth street to Trunk 36 at Elm avenue.

36-37. From junction of Trunks 36 and 37 at Elm avenue, along prolongation of Elm avenue to Interceptor IV. on prolongation of Tenth street.

38. From Central avenue, along Richmond road and Barton avenue to Interceptor IV. at 30-foot contour.

39. From Jackson avenue, north along Richmond road, and east along Liberty avenue to Interceptor IV. at 30-foot contour.

40. From about 20-foot contour, near New Dorp lane, north and east to junction with Trunk 41 at New Creek.

41. From near railroad, Dongan Hills, east to Trunk 40.

40-41. From junction of Trunks 40 and 41, north to Sea View avenue Pumping Station.

42. From South Beach, south, parallel to shore, to Sea View Avenue Pumping Station.

40-41-42. Sea View Avenue Force-Main. From Sea View Avenue Pumping Station west along Sea View avenue to Interceptor IV. at 30-foot contour.

43. From 300-foot contour, near Ocean Terrace road, at summit of ridge, east down valley of stream to Interceptor IV. at 30-foot contour.

44. From 100-foot contour, near Grasmere, south along valley of stream and Parkinson avenue to Interceptor IV.

45. From 100-foot contour, on Fingerboard road, east and south along Fingerboard road and Sand Lane road to Interceptor IV.

46. From about 100-foot contour, south along Sea avenue to Interceptor IV. at Old Town avenue.

Division E.

47. From 60-foot contour, on Nelson avenue, southeast along Nelson avenue, nearly to shore of Great Kills Bay; thence following shore to junction with Trunk 48.

48. From 60-foot contour, along valley of small stream to Trunk 47, near shore of Great Kills Bay.

47-48. From junction of Trunks 47 and 48, northeast to junction with Trunk 49 at Mill Pond, near head of Great Kills Bay.

49. From 40-foot contour, near railroad at Courthouse, east and south along stream to Trunk 47-48 at Mill Pond.

47-48-49. From junction of Trunk 47-48 with Trunk 49, at Mill Pond, east to Great Kills Pumping Station.

50. South along shore from Elm Tree Beacon to Great Kills Pumping Station.

51. North along Great Kills Peninsula to Great Kills Pumping Station.

47-51. Outfall Section. From Great Kills Pumping Station, southeast to water 12 feet deep, 5,000 feet off shore.

Division F.

52. From 60-foot contour, opposite mouth of Great Kills Bay, south to shore, following shore southwest to junction with Trunk 53 at Barclay avenue.

156 53. From 60-foot contour, near Amboy road, south along small stream, parallel to Barclay avenue to junction with Trunk 52.

54. From 80-foot contour, near railroad, following valley of small

stream south to junction with Interceptor V. at Latourette's Pond, near shore.

55. From 100-foot contour, south along valley of stream, to junction with Interceptor V. at Wolfs Pond, near shore.

56. From 120-foot contour, near Wood Row, west and south to junction with Trunk 57, at Maguire avenue, near fork of Lemon Creek.

57. From 100-foot contour, west and south to junction with Trunk 56, at Maguire avenue, near fork of Lemon Creek.

56-57. From junction of Trunks 56 and 57, south and east along valley of Lemon Creek, to a point nearly opposite Findlay avenue.

58. No trunk has been designed for Area 58, the flow from which will be considered as entering Trunk 56-57 at a point opposite Findlay avenue.

56-57-58. From bend in Lemon Creek, opposite Findlay avenue, along valley of Lemon Creek, to Seguine's Point Pumping Station.

Division G.

59. From Rossville, west and south along shore of Arthur Kill to Kreischerville Relay Pumping Station, at junction with Trunk 60, at mouth of stream opposite Boynton Beach, New Jersey.

60. From 100-foot contour, near Pleasant avenue, west along valley of stream to Kreischerville Relay Pumping Station, at junction with Trunk 59.

61. From 100-foot contour, west to south end of Kreischerville Force-main.

62. From 80-foot contour, south to Interceptor VI., near Mill Creek.

63. From about 100-foot contour, south of Sharrott's road, south and west to Interceptor VI., at junction with Trunk 62.

64. From near Hopkins avenue, Tottenville, north along shore of Arthur Kill to Mill Creek Pumping Station.

65. From 60-foot contour, near summit of ridge, along valley of Mill Creek to Mill Creek Pumping Station.

66. From 40-foot contour, near summit of ridge, south to shore of Prince's Bay; following shore southwest to Red Bank Pumping Station.

67. From near Bay Cliff Lake, at summit of ridge, south to shore, near southern extremity of island; northeast along shore to junction with Trunk 68 at Central avenue.

68. From summit of ridge, near 60-foot contour, south along Central avenue, to junction with Trunk 67 at shore.

67-68. From Central avenue, northeast along shore to Red Bank Pumping Station.

Division H.

69. From near Fresh Kills road, following line of Richmond Creek, to Richmond Creek Pumping Station, near Fresh Kills Bridge.

70. From 10-foot contour, near Eltingville road, east and north to Richmond Creek Pumping Station.

157 71. From 20-foot contour, near Greenridge avenue, and Fresh Kills road, northeast to west end of Richmond Creek Force-main, near bend in Richmond Creek.

72. From 40-foot contour, near Washington avenue, north along valley of small stream, to junction with Trunk 73, about 2,000 feet from Fresh Kills.

73. From spur of ridge, west of Trunk 72.

72-73. From junction of Trunks 72 and 73, north to Interceptor VII., near fork of Fresh Kills.

74. From 40-foot contour, near Fresh Kills road, and Huguenot avenue, north, parallel to shore of Arthur Kill, to junction with Interceptor VII. on Fresh Kills, opposite Lake's Island.

75. From about 40-foot contour, at Willow Brook, following the Brook and east shore of Fresh Kills Creek, west and south to junction with Trunk 76 at mouth of Springville Creek.

76. From near 40-foot contour, on Rockland avenue, following Springville Creek west to Fresh Kills Creek.

77. From 20 foot contour, near Old Turnpike, south along valley of stream, and west along Richmond Creek to Fresh Kills Pumping Station.

78. From Union avenue, southwest, generally parallel to Fresh Kills Creek, to west end of Fresh Kills Force-main.

79. No trunk has been designed for Area 79, but its flow will drain directly into the pump-well of the Lakes Island Pumping Station.

Division I.

80. From near Union avenue, west along valley of Neck Creek to shore, following shore north to junction with Trunk 81 at mouth of small creek, opposite Pralls Island.

81. From 10-foot contour, west along valley of creek to Trunk 80.

80–81. From junction of Trunks 80 and 81, north along shore of Arthur Kill to Bloomfield Purification Works, at a point north of Pralls Island.

82. From 10-foot contour, near Simonson avenue, west along valley of Old Place Creek to junction with Trunk 83.

83. From 10-foot contour, near Decker avenue, north to Trunk 82 at Old Place Creek.

84. From 10-foot contour, near South avenue, west along Bridge Creek to Western avenue, southwest to Old Place road, across Old Place Creek to Junction with Interceptor IX.

85. From near mouth of Old Place Creek, south along shore of Arthur Kill to Bloomfield Purification Works.

Design of Trunk Sewers from Each Area.

The daily flow of sewage has been assumed as equal to the water consumption, and for lack of more definite information, this latter figure has been taken at 125 gallons per capita per day.

Sewers are in all cases designed for maximum sanitary flow, as determined from the assumed future population and per
158 capita water consumption. No allowance has been made for storm flow in this district. Ground water is taken uniformly at 0.003 second feet per acre.

Future population has been assumed as suburban in character, with a density of 25 persons per acre, uniformly distributed over the entire district.

For the peak load upon the system, the maximum flow is assumed to be at a rate which would carry off half the daily flow in eight hours.

Trunks and branches, in which the flow is apt to vary greatly from the assumed maximum, owing to the comparatively small areas served, and liability to local influences, have been designed to carry the assumed maximum flow when only half full, in order to provide for contingencies, while the interceptors, in which the flow will equalize and be much more uniform, have been designed to carry the assumed maximum flow when eight tenths full.

The design for size, grade, etc., has been made from the diagrams in Swan & Horton's "Hydraulic Diagrams," and from a diagram of hydraulic elements for circular sections, in the same book, the discharges and velocities for the sewers 0.8, 0.5, 0.2 and 0.1 full, have been computed.

Except in very few cases, the grades have been taken so as to insure a velocity of 3.0 feet per second or greater, which will give a velocity of 1.8 feet per second when flowing 0.2 full, or at only 0.085 full discharge. This velocity is thought to be sufficient for self-cleansing purposes.

In all siphons, force-mains and outfalls, an effort has been made to secure a uniform velocity of 3.0 feet per second, as nearly as commercial sizes of cast iron pipe will permit.

All designs contemplate circular sections only.

The datum plane for all elevations is the plane of Mean Sea Level at Sandy Hook, as established by the U. S. Coast and Geodetic Survey.

When elevations are given, they refer invariably to the invert of the sewer, unless otherwise specifically stated.

In all cases where the depth of a sewer is mentioned, the depth to the inner top is meant; i. e., the depth to the invert, less the diameter.

In all possible cases, an earth covering of six feet over the inner top of the sewers has been allowed. In no case has this covering been reduced to less than four feet.

Wherever possible, the grades have been taken so as to fit the slope of the ground, but where this would give velocities in excess of about 7.5 feet per second, or where a portion of the ground has a slope flatter than the remainder, a flat grade has been adopted, and the sewer left at a uniform depth of about four to six feet by drop manholes installed at convenient intervals.

At the low-lying portions of the Borough, it is assumed that the

finished grade of the surface, behind the bulkhead wall, will be about 7.35 feet above the datum of Mean Sea Level, or 5.0 feet above Mean High Water (Dock Department).

Whenever possible, at the junction of a trunk with an interceptor the invert of the former is elevated above that of the latter by an amount equal to the difference of diameter, or by half the diameter of the interceptor, if the difference of diameter exceeds this. This is done in order to preserve an unbroken invert in the interceptor, and thus prevent eddies and consequent deposits of suspended solids, and to prevent backing up into small trunks. This
159 elevation is not given where two trunks unite to form an interceptor, nor, obviously, where the two sewers are of the same diameter.

Where an existing storm sewer is intercepted, the interceptor is designed to take only the dry weather flow, and the remaining length of the storm sewer will be maintained and utilized as a storm overflow, to prevent choking of the interceptor.

In the following table are summarized the principal elements involved in the design of these trunk sewers, namely, length, total fall, elevation of invert at upper end, tributary area, slope, maximum diameter, maximum discharge, and velocities and discharges at 0.8 and at 0.2 full.

Trunk No.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Tributary area, acres.	Slope 1, foot in—	Maximum diameter, feet.	Maximum discharge, sec. ft.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full. Velocity, sec. ft.	Sewer 0.2 full. Discharge, sec. ft.

† No trunk designed.

164 Design of Intercepting Sewers.

The design of these sewers is determined by the available slope and by the points of entrance of the various trunk sewers. Sizes are based upon normal flow with sewers .8 full. To facilitate reference, the nine interceptors have each been subdivided into sections designated by letters and beginning at the upper end in each case. These sections are described as follows:

Divisions A and B.

Interceptor I.

a. From Columbia street along Post avenue, Elizabeth street, Castleton avenue, Broadway, two intervening streets and Henderson avenue to junction with Trunk 8 at Rement avenue.

b. From Rement avenue, east along Henderson avenue, along 30-foot contour and Richmond terrace to junction with Trunk 9 at Lafayette avenue.

c. From Lafayette avenue, along Richmond terrace to junction with Trunk 10 at Jersey street.

d. From Trunk 10 at Jersey street, along Richmond terrace to Church street.

e. From Church street, along Richmond terrace, Jay street, South street, Stuyvesant place, Central avenue to Arietta street.

f. From Central avenue, along Arietta street, Van Duser, Hanna street, St. Paul's avenue, Clinton, Van Duser, Wright and Boyd streets, across to junction with Trunk 13-14-15 at Canal street.

g. From Canal street, along Riker and Tompkins streets, and various other streets at about the 30-foot contour to Trunk 16 at Willow avenue.

h. From Willow avenue, south to Maple avenue; thence along Maple and New York avenues to junction with Trunk 17 at Pennsylvania avenue.

i. From junction with Trunk 17, east along Pennsylvania avenue to shore.

j. Outfall Section—From foot of Pennsylvania avenue, east to water 50 feet deep in channel.

Divisions C and D.

Interceptor II.

a. From Rockland avenue, following 50-foot contour south to junction with Trunk 20, south of Richmond Hill road.

b. Following 50-foot contour south from Trunk 20 to junction with Trunk 21, near Old Mill road.

c. From Trunk 21, following 40-foot contour eastward around spur of ridge to junction with Trunk 22-23 at Richmond Creek.

d. Richmond Creek Siphon—From junction with Trunk 22-23, east under Richmond Creek to Interceptors III. and IV.

Interceptor III.

a. From Trunk 25, following approximately the 50-foot contour to junction with Trunk 26 at Greenridge avenue.

b. From Greenridge avenue, following 50-foot contour east to junction with Trunk 27-28, near small creek.

c. Eltingville Road Siphon—From junction with Trunk 27-28, east under stream to Trunk 29-30.

165 *d.* From Trunk 29-30, following the 40-foot contour northeast to junction with Trunk 31, near fork of stream.

e. From Trunk 31, following 40-foot contour north to junction with Trunk 32, south of Clark avenue.

f. From Trunk 32, north to east end of Richmond Creek Siphon.

Interceptor IV.

a. From east end of Richmond Creek Siphon, east to junction with Trunk 33, north of Clark avenue.

b. From Trunk 33, north and east to junction with Trunk 34-35 on Amboy road.

c. From Trunk 34-35, at Amboy road, east to Tenth street, New Dorp, following Tenth street to junction with Trunk 36-37 at prolongation of Elm avenue.

d. From Trunk 36-37, north along 30-foot contour, Lincoln avenue and Thompson street to junction with Trunk 38 at Barton avenue.

e. From Trunk 38, at Barton avenue, following 30-foot contour to junction with Trunk 39 at Liberty avenue, Dongan Hills.

f. From Trunk 39, at Liberty avenue, north along 30-foot contour to junction with Sea View Avenue Force-Main.

g. From Sea View Avenue Force-Main, north along 30-foot contour to Trunk 43, south of Burgner avenue.

h. From Trunk 43, north and east along 30-foot contour to Trunk 44 on Parkinson avenue.

i. Along 20-foot contour, from Trunk 44 at Parkinson avenue to Trunk 45 at Sand Lane road.

j. From Trunk 45, on Sand Lane road, east along 20-foot contour and Old Town avenue to junction with Trunk 46 on Sea avenue.

k. From Old Town avenue, south along prolongation of Sea avenue to shore.

l. Outfall Section—From foot of Sea avenue, prolonged to shore, east 3,500 feet to water 50 feet deep in channel.

Division E. Division F.

Interceptor V.

a. From junction of Trunks 52 and 53, at Barclay avenue, following shore south and west to junction with Trunk 54, at Latourette's Pond.

b. From Latourette's Pond, following shore southwest to junction with Trunk 55, near Wolf's Pond.

c. From Wolf's Pond, southwest along shore to Seguine's Point Pumping Station.

d. From Seguine's Point Pumping Station, southeast to water 21 feet deep, 800 feet off shore.

Division G.

Interceptor VI.

a. Kreischerville Force Main—From Kreischerville Relay Pumping Station, at south end of Trunk 59, south, parallel to shore of Arthur Kill to junction with Trunk 61, at Kreischer street, Kreischerville.

b. From south end of Kreischerville Force-Main, south along shore of Arthur Kill and east along Mill Creek to junction with Trunks 62 and 63, near Richmond Valley road.

166 *c.* Mill Creek Siphon—From Junction of Trunks 62 and 63, south under Mill Creek to Mill Creek Pumping Station, on south bank of creek.

d. Mill Creek Force-Main—From Mill Creek Pumping Station, southeast to summit of ridge.

e. From Mill Creek Force-Main, at summit of ridge, southeast to Red Bank Pumping Station, at shore.

f. Gravity Outfall Section—From Red Bank Pumping Station, southeast to 21 feet of water, 1,600 feet off shore.

Division H.

Interceptor VII.

a. Richmond Creek Force-Main—From Richmond Creek Pumping Station, near Fresh Kills Bridge, west under Mill Pond outlet to junction with Trunk 71, near bend in Richmond Creek.

b. From junction with Trunk 71, at west end of Richmond Creek Force-Main, west along Richmond Creek to junction with Trunk 72-73, near fork of Fresh Kills.

c. From junction with Trunk 72-73, west to junction with Trunk 74, at a point on Fresh Kills opposite Lake's Island.

d. Fresh Kills Siphon—From junction with Trunk 74, on east bank, west under Fresh Kills to Lake's Island.

e. From west end of Fresh Kills Siphon, west to Lake's Island Purification Works, on the shore of Arthur Kill.

Interceptor VIII.

a. From junction of Trunks 75 and 76, at Springville Creek, south to Fresh Kills Pumping Station.

b. Fresh Kills Force-Main—From Fresh Kills Pumping Station, northwest under Fresh Kills Creek to Trunk 78, north of Little Fresh Kills.

c. From west end of Fresh Kills Force-Main at junction with Trunk 78, southwest to north bank of Little Fresh Kills.

d. Little Fresh Kills Siphon—From north bank, southwest under Little Fresh Kills to Lake's Island.

e. From south end of Little Fresh Kills Siphon, southwest to Lake's Island Purification Works, on shore of Arthur Kill.

f. Outfall Section from Purification Works—From Lake's Island Purification Works west to 21 feet of water in Arthur Kill, 800 feet off shore.

Division I.

Interceptor IX.

a. From junction of Trunks 82 and 83, west along Old Place Creek to junction with Trunk 84, near Old Place road.

b. From junction with Trunk 84, southwest to Bloomfield Purification Works, on shore of Arthur Kill, north of Prall's Island.

c. Outfall Section from Bloomfield Purification Works—From Bloomfield Purification Works west to 21 feet of water in Arthur Kill, 750 feet off shore.

The total length, total fall, in each section, elevation of invert at upper end, tributary area, slopes, maximum diameter, maximum discharge and discharges at .8 and .2 full for each section of these nine interceptors are summarized below:

Section.	Length, feet.	Total fall, feet.	Elevation of invert, upper end.	Tributary area, acres.	Slope 1, foot in—	Maximum diameter, feet.	Maximum discharge, feet.	Sewer 0.8 full. Velocity, sec. ft.	Sewer 0.8 full. Discharge, sec. ft.	Sewer 0.2 full Velocity, sec. ft.	Sewer 0.2 full Discharge, sec. ft.

170 Pumping Stations and Force Mains.

These plans contemplate the establishment of eleven pumping stations, the ultimate maximum capacity and the approximate locations of which are tabulated below. The capacities given are net horse-power without reference to efficiency and refer to total lift between pump well level and elevation of upper flow-line or ordinary maximum high tide as the case may be and include estimated loss of head in force-mains.

Table of Pumping Stations.

Designation.	Serving.	Discharge, sec. ft.	Lift, feet.	Power developed, h. p.
Van Pelt avenue relay	Trunk No. 1	3.44	5.82	2.40
Sea View avenue	Sea View avenue force main	18.64	27.56	58.30
Great Kills	Outfall E	20.20	16.17	37.40
Seguine's Point	Outfall F	34.14	13.54	52.50
Red Bank	Outfall G low level lift	12.25	14.13	22.30
Mill Creek	Mill Creek force main	26.84	42.16	128.90
Kreischerville	Kreischerville force main	12.11	16.48	22.65
Lake's Island	Lakes Island purification works.	50.75	16.61	95.90
Richmond Creek	Richmond Creek force main	6.73	17.70	13.53
Fresh kills	Fresh Kills force main	19.61	6.79	15.1*
Bloomfield	Bloomfield purification works	40.13	16.06	76.00
Total power required				525.01

There will be six force-mains in the ultimate development of this plan, the essential details of which are tabulated below:

Table of Force-Mains.

Designation.	Length, feet.	Max. disch., sec. ft.	Vel., ft. per sec.	Diam., feet.	Elev. pump well.	*Lift, feet.	Power required, h. p.
Columbia St., Trunk 1-2-3	2,240	18.01	2.55	3.0	—12.00	45.87	93.85
Sea View Ave., Trunk 40-41-42	5,280	18.64	2.64	3.0	—10.00	27.56	58.30
Kreischerville, Intercept. VI. *a*	2,640	12.11	2.84	2.33	—12.00	16.48	22.65
Mill Creek, Intercept. VI. *d*	3,560	26.84	2.79	3.5	—10.00	42.16	128.90
Richmond Creek, Intercept. VII. *a*	2,100	6.73	3.09	1.67	—10.00	17.70	13.53
Fresh Kills, Intercept. VIII. *b*	3,040	19.61	2.77	3.0	—10.00	6.79	15.13

* NOTE.—The lift as given includes the loss of head in the pipe.

171 Siphons.

Five inverted siphons will be required located as follows:

Richmond Creek Siphon (Interceptor II., section *d*)—From junction Trunk 22-23, east under Richmond Creek to Interceptors III. and IV.

Eltingville Road Siphon (Interceptor III., section *c*)—From junction with Trunk 27-28, east under stream to Trunk 29-30.

Mill Creek Siphon (Interceptor VI., section *c*)—From Junction of Trunks 62 and 63, south under Mill Creek, to Mill Creek Pumping Station, on south bank of creek.

Fresh Kills Siphon (Interceptor VII., section *d*)—From junction with Trunk 74, on east bank, west under Fresh Kills to Lake's Island.

Little Fresh Kills Siphon (Interceptor VIII., section *d*)—From north bank, southwest under Little Kills to Lake's Island.

The essential details of these siphons are tabulated below:

Table of Siphons.

Designation.	Location.	Length, feet.	Diameter, feet.	Maximum discharge.	Velocity, feet per second.	Loss of head, feet.

Points of Discharge, Pollution of Waters, and Purification Necessary.

The seven outfall sewers have been described as the last section in each case of the seven interceptors. Their location is more definitely shown upon the accompanying map. The question of the effect of these discharges upon the surrounding waters and of the purification necessary for the prevention of nuisance, is discussed fully in our general report upon the pollution of the waters of New York Harbor and the purification of sewage entering these waters. For the reasons more fully discussed in that report, no purification is thought necessary for Outfalls A-B, C-D, E-F and G. Outfalls H and I both discharge into the Arthur Kill. Owing to the comparatively poor tidal circulation available at these points, the small volume of water in which the discharge takes place, and the relatively large amount of pollution at present existing in these waters, it is recommended that a partial purification of the sewage from both of these outfalls be undertaken. A process of short-time sedimentation and of forced aeration similar to that employed by us in our Brooklyn experiments will probably be found satisfactory and sufficient.

The further details of the design of these outfall sewers which was omitted from the table of interceptors is summarized below:

174 *Special Report on the Oxygen Content of Sea Water as a Standard for Measuring Sewage Pollution Submitted to the Board of Estimate and Apportionment July 1, 1910.*

175 BOARD OF ESTIMATE AND APPORTIONMENT,
CITY OF NEW YORK, June 27, 1910.

Hon. William J. Gaynor, Mayor, Chairman of the Board of Estimate and Apportionment.

SIR: Colonel William M. Black, who is making an investigation of the location of sewer outlets and of the disposal of sewage for the Board of Estimate and Apportionment, and Professor Phelps, who is associated with him in this work, have handed me a report dated June 7, in which they point out the important bearing which the amount of unpolluted water daily entering the harbor of New York has upon the sewerage problem, and the lack of definite information upon this subject.

There is no question but that the starting point of any investigation designed to offer a solution of this problem must be a determination of the capacity of the harbor to take care of the sewage discharged into it without permitting the water to become so polluted as to be offensive. While some data has been collected by the United States Coast and Geodetic Survey and by the New York Bay Pollution Commission, the information is very meagre. The report of the Metropolitan Sewerage Commission has not been published, but I understand that this Commission has not secured sufficient information along these lines to lead to a definite conclusion. This would seem to be an excellent line of investigation for this Commission to follow, and I would recommend that the report of Colonel Black and Professor Phelps be sent to the Metropolitan Sewerage Commission, with the request that the Commission follow the lines of investigation suggested in the report and furnish the Board with such information as it can secure.

Respectfully, NELSON P. LEWIS,
Chief Engineer.

176 NEW YORK CITY, June 7, 1910.

Mr. Nelson P. Lewis, Chief Engineer, Board of Estimate and Apportionment, No. 277 Broadway, New York, N. Y.

DEAR SIR: The question of the proper disposal of the sewage of New York embraces many problems interesting from an engineering and an economic standpoint. For the present and probably for many years to come water carriage is and will be the most economical method of conveying sewage from the points of production to common points of disposal. To-day, the sewage is discharged at many points into the waters bordering the city. These waters form the harbor of New York and are the source of its greatness and even of its life. Their preservation in a condition fit for commerce is essential and no expenditures necessary to that end can be considered too great. The practical business sense of the American citizen only requires that he be convinced of the necessity for a given work in order to induce him to provide the means for its execution.

To-day the condition of purity of these waters is a subject of controversy. Some eminent engineers declare that their capacity for receiving and disposing of sewage is so great as to suffice not only for the needs of the population now found in the drainage area, but also for the probable increase of that population during many years. Others, professing equal technical knowledge, claim that the waters are now overtaxed and that an inadmissible and dangerous degree of pollution already exists. The former cite in support of their opinions analyses of water taken from portions of the harbor which show practically a normal degree of purity. The latter show analyses of specimens taken from other parts which show septic conditions. Both are honest in their professions, but with the system now in use by which sewage is discharged without an attempt at general distribution and without regard to the volume of flow or the circulation of the water in the vicinity of the outlets, it is natural that different localities should show to-day entirely different conditions, and that it is only necessary to make a judicious choice of locality in order to obtain an apparently irrefutable argument in support of either side of the controversy.

In so far as known, no attempt has been made as yet to consider the subject as a whole and to determine whether the capacity of the entire body of water is adequate to the task of receiving and purifying continously the sewage of the drainage area tributary to these waters.

It is evident that if the capacity be adequate, the problem resolves itself into a question of proper distribution, so that no part of this natural purification machine shall be overloaded. If it be insufficient for the work, then the load must be reduced by purifying all of the sewage partially, or by purifying a portion to a higher degree. It is quite conceivable that with improper distribution a part of the machine of limited capacity, such as Gowanus Basin, Newtown Creek or the Harlem River might be overloaded and break down, as evidenced by septic conditions, while another part does little or no work. It is further evident that with proper distribution, purification of a part to the necessary degree can be limited to and carried on at points where the physical conditions are such
177 as to permit the work to be done with the greatest economy, thus making it possible for the sewage from other localities, under conditions less advantageous for this class of work, to be discharged safely without treatment.

It is economically unwise not to take the fullest advantage consistent with safety of the great purification machine provided by nature. To do this to the best advantage, the question should be trated from the standpoint of the interests and requirements of the population of the entire drainage area, irrespective of the artificial political boundary lines. If legal conditions make this impossible for the present, then minimum subdivision should be made by the corporate limits.

In other words, if the supply of oxygen provided daily to the waters of New York Harbor is sufficient to reduce a portion of the dose of sewage daily discharged into them without causing an undue reduction of their contained oxygen (and the consequent produc-

tion of conditions of pollution), it is evident that artificial purification is required only for the remainder of the sewage, and that the purification of this excess volume can then be carried on to the extent required at those points of discharge where that work can be done most economically and advantageously to the entire community. It would then follow that, in certain districts of the city, sewage could be discharged with proper distribution into the waters without treatment, because of the treatment given elsewhere to other portions of the total daily discharge, and that the cost of the treatment wherever made should be borne by all citizens benefited, that is, by the inhabitants of all districts discharging sewage into the harbor waters. When this general treatment is made, it should not be a borough, or a ward, or a district question. Only by broad general treatment can the best and most economical results be obtained.

The ultimate disposal of sewage, the resolution into its primary elements, like that of all organic waste products, is reached by oxidation. This is true, whether the resolution take place in the air, under the earth or in the water. Water in its normal condition contains in solution a certain quantity of oxygen. About 30 per cent. of this dissolved oxygen can be removed without practical detriment to the limpidity of the water, or to its ability to support major fish life. When an unstable organic substance is discharged into water, oxidation begins at once and continues until the resolution of the substance into its elements has been made. During this process the water parts with its dissolved oxygen. If the circulation of the water be sufficient to divide the loss through a sufficient volume, no harm results, and the water gradually regains its normal oxygen contents from the atmosphere. Should the loss of oxygen be greater than 50 per cent., the water becomes offensive and major fish life disappears. Septic conditions are reached when the oxygen has been exhausted. In these conditions none but the lowest forms of life are possible and offensive gases are evolved.

As stated, the normal supply of dissolved oxygen is restored to exhausted water from the atmosphere. This process is slow in quiet waters. In streams, especially when the flow is swift, and where natural or artificial waterfalls exist, it is more rapid. For example, in 1900, the late Prof. Palmer found that the water of the Chicago Drainage Canal, above the Bear Trap Dam, at Lockport, Ill.,
178 contained 5.9 per cent. of dissolved oxygen, while 200 yards below the dam the aeration produced at the dam had increased the proportion of dissolved oxygen to 70 per cent. of saturation (Lederer, Treatment of Sewage).

In New York Harbor other sources than the reaeration from the atmosphere supply the greater part of the oxygen needed for the daily work of purification.

The sources of supply are as follows:

(*a*) The volume of normal sea water brought into the harbor daily by tidal action.

(*b*) The volume of fresh water discharged from streams emptying into the harbor.

(*c*) Rainfall reaching the harbor directly or from immediate surface drainage.

(*d*) A portion of the city water supplies.

(*e*) Reaeration by surface absorption of oxygen.

The data available from which to obtain a measure of the supply of normal sea water brought in by the tides are found in the publications of the United States Coast and Geodetic Survey relating to the circulation of the sea in New York Harbor. The investigations of the New York Bay Pollution Commission confirm and illustrate the conclusions reached by the United States Coast Survey measurements.

Gaugings of the flow through the Sandy Hook entrance, the Narrows and the North and East Rivers were made in 1886 and earlier years. From several sets of careful measurements made opposite 23d street, East River, Prof. Mitchell found that there was a preponderance of flow westward (south through the East River of about 440,000,000 cubic feet per tide. The conclusion has since been questioned, but inasmuch as the doubt was raised as a result of a theoretical discussion, without further measurement, and since other direct measurements seem to show the preponderance of flow westward, the writers accept Prof. Mitchell's conclusions. At Sandy Hook the preponderant volume of flow is to the south (outward).

To determine an approximate solution of the problem of the amount of oxygen available daily in the East River, the following method is being followed by the writers:

The calculations of the United States Coast and Geodetic Survey show for an average tide the easterly flow through the East River, opposite Old Ferry Point. When this flow begins the water level is at 4.26 feet above the mean low water plane and falling. The mean velocity is given for each lunar hour. While the easterly flow continues, the tide falls from 4.26 feet above mean low water to mean low water, and then rises to 4.47 feet above mean low water. The probable effects to the east of Old Ferry Point are that at the end of the easterly flow the entire body of water in the channel east to Stepping Stone Light, plus the tidal prism of the bays at the side, to the elevation 4.47, is composed of water, more or less polluted, which had flowed out past Old Ferry Point.

When the westerly current sets in, the tide is rising, the flow is through the channel and into the bays. As the tide rises, the tidal prism of the bays is completed from the channel and the volume of water flowing back past Old Ferry Point consists of the water
179 which had flowed out, admixed with a volume of normal sound water equal to the amount used in filling the tidal prisms of the side bays, plus the preponderance of westward over eastward flows in the East and Harlem Rivers. The volume of this normal sound water thus entering (about 1,000,000,000 cubic feet) gives the measure of the new supply of oxygen provided by one tide, and of this supply 30 per cent. can be used with safety in sewage purification. Before the tide turns again this water has been divided between the East and Harlem Rivers and has entered into its work in the harbor.

For the Sandy Hook entrance the problem is more complex. Since the preponderance of flow is southerly (outward), and since at any one flood tide the fresh sea water is carried but a limited distance into the upper bay, it would seem that, excepting in the lower bay, but a very limited admixture took place. Due, however, to a marked underrun of the northerly flow under the ebb current at the beginning of the flood and for some time before the change in current direction has occurred at the surface, the normal sea water is carried into and distributed through the upper bay and lower Hudson.

For the determination of the volumes of flow the only data available is that supplied by the United States Coast and Geodetic Survey and that obtained from the Engineer Department of the Army. In 1886 and prior years, the Coast Survey made a number of careful measurements of the flow at various sections in the Sandy Hook channels, in the Narrows, the Hudson and the East Rivers. The results were calculated and reported on by the late Prof. Henry Mitchell, whose wide experience made him a most competent investigator. The investigations were confessedly incomplete, for the problem is very complicated and difficult. A lack of funds has prevented their continuation. Other calculations based on the observations then made and on a theoretical discussion have since been made by Dr. Harris of the Coast and Geodetic Survey. Dr. Harris' conclusions as to the relative volumes of flow north and south through the East River differ from those of Prof. Mitchell, in that Dr. Harris believes that the preponderance of southerly flow is much less than that found by Prof. Mitchell. Dr. Harris' discussion assumes that the velocities of the tidal currents follow strictly the laws of variation through a section as do river current velocities. This assumption is not believed to be fully supported by the scanty records of observations available—and the writers believe that Prof. Mitchell's conclusions are probably more nearly correct. The records of surface velocities published in the Atlantic Coast tide tables, as well as the float observations made by the New York Bay Pollution Commission, in so far as reported, would seem to support this opinion. The question is so important to New York City that it is hoped that provision will be made for further study.

The investigations of the Engineer Department give the only data for the tidal conditions in the Harlem River. From them it would appear that there is a resultant flow in the Harlem toward the Hudson. The Department is now making a further study of the question in connection with work contemplated for Hell Gate and its neighboring channels, Little Hell Gate and the Bronx Kills, and more data will soon be available. New sets of observations and measurements are needed near Old Ferry Point, at the extremities of the Harlem River, in the East River, south of Hell Gate,
180 near the Battery, and in Buttermilk Channel, at the Narrows and in the Sandy Hook Bar channels—sufficient to determine with greater accuracy the daily supply to and distribution in the harbor of the normal sea water.

The volume of fresh water discharge of the streams into the har-

bor is known approximately. Since the greater part of these streams must care for the sewage from a population along their basins, little or no help for the harbor can be expected from them. Care must be taken that they be not polluted to such a degree as to add to the work which the harbor waters properly may be expected to perform. To-day the Passaic flow is probably distinctly detrimental. If care be not taken that of the Hudson may soon be in the same condition. Newtown Creek and Gowanus Basin are notoriously septic and add to the harbor's burdens. Recent analyses of the Harlem waters show conditions at times nearly as bad. It is safe to say that the Passaic, Newtown Creek, Gowanus Basin and the Harlem are overloaded.

The oxygen supply from the rainfall can be calculated approximately. In a very large part of the drainage area the run off is collected in the sewers and this, with the excess of the drinking water supply, is available for useful work, excepting when the detention in the sewers is long enough to produce septic conditions and a waste of oxygen before discharge. These conditions undoubtedly exist in many of the older and badly designed sewers. In the City of Washington, for example, the character of the sewage effluent, collected at the disposal pumping station, is to-day remarkably fresh, due to the fact that in recent years, the older sewers of that city have been reconstructed and no long detention of sewage in them now exists. The contrast between the character of the Washington sewage and that of Boston, for example, is marked. In New York, the length of the sewers is generally short, and there is little or no reason why the time elapsing between collection and discharge should not be short. If it were, the work of the harbor waters would be diminished.

For convenience, what may be termed normal American sewage is assumed to be of a dilution equal to a consumption of 100 gallons of water per day per inhabitant. The absolute composition of sewage must vary for each locality and with the changing seasons, depending on the conditions of living, the proportion of manufacturing establishments per inhabitant, and other causes. But in the larger cities there is a degree of similarity in composition and, therefore, that what is termed normal American sewage, as described by Profs. Winslow and Phelps, can be taken as representative, for calculation, in the absence of exact information. It is evident that when water consumption is at the rate of more than 100 gallons per day per inhabitant, and when the rainfall is collected in the sewers the dilution is greater, and by that dilution is supplied oxygen which is available for sewage resolution. In New York to-day data is lacking. There is no record attainable of water consumption by districts; no record of the volume of sewer discharge, either per sewer outlet or per drainage area; no record of average sewage composition and little from which the population per drainage area can be computed. Such data is required for a satisfactory discussion of the problem of sewage disposal.

181 The determination of the supply of dissolved oxygen obtained by reaeration from the atmosphere is too difficult to admit of more than an approximation. Dr. W. E. Adeney, of Eng-

land, has propounded a certain hypothesis of the rate of reaeration of harbor waters, based on a series of laboratory experiments. His work is valuable in starting investigations into this subject, but his conclusions seem erroneous.

We are now engaged in further experimentation and investigation on the same subject. At best, however, little more can be learned than the probable rate of surface absorption of oxygen by still water and its rate of diffusion to the depths below. The important effects of wind and of surface agitation by passing shipping can only be guessed. Fortunately, these effects are beneficial, and if not overestimated may be considered a valuable factor of safety. Direct observations in the harbor itself would be of much value.

It is universally admitted that the harbor must not be permitted to reach a condition of pollution which will be detrimental to human health, or which will deter shipping from using the port. The exact degree of purity to be required has never been agreed on, nor is there any uniformity of opinion to-day as to what is the general condition of the harbor as regards allowable pollution. Localities are admittedly bad and costly provisions are being taken toward improving the local conditions in at least one of these, Gowanus Basin.

It is the belief of the writers that the waters of the harbor should be maintained in such a condition as to support major fish life everywhere, and that this condition requires that in no part shall there be found less than probably about 70 per cent. of the saturation quantity of dissolved oxygen.

When the importance of the subject and the vast amount of capital involved in the proper solution of the question are considered, it would appear self-evident that ordinary business sense would require the same careful investigation into existing conditions, into the necessity for a change, and into the most economical method of attaining the desired results, as is made for proposed betterments in private business undertakings.

The writers are endeavoring to find partial solutions to the problems with the limited resources available to them. They send you this letter in the hope that further interest may be awakened in this important subject and that a presentation of the problem as it appears to them, of the methods of solution suggested, and of the difficulties encountered may lead to a further discussion and to such official action as may permit a full and careful investigation to be made and a more accurate determination of the facts to be attained.

Very respectfully,

W. M. BLACK.
EARLE B. PHELPS.

I hereby certify that the foregoing are true copies of reports presented to the Board of Estimate and Apportionment at its meetings on April 22, 1910, June 17, 1910, July 1, 1910, January 12, 1911, March 9, 1911 and March 23, 1911, and printed in the minutes (Public Improvement matters) of the meetings of the Board held on said dates.

W. H. LANG,
Secretary Board of Estimate and Apportionment.

June 20/12.

1 COMPLAINANTS' EXHIBIT No. 137.

James D. Maher, Commissioner.

4080.

Report on Sewage Disposal of Orange, Montclair, and East Orange.

James H. Fuertes, Consulting Engineer, New York.

October 14, 1911.

2 *Report on Sewage Disposal of Orange, Montclair, and East Orange.*

James H. Fuertes, Consulting Engineer, New York.

October 14, 1911.

3 NEW YORK, October 14th, 1911.

To the Joint Committee on Sewage Disposal of Orange, Montclair, and East Orange.

GENTLEMEN: Pursuant to your request I submit herewith a report on the disposal of the sewage of Orange, Montclair and East Orange, with recommendation as to the most suitable, efficient and economical plan to be adopted, together with estimates of cost of constructing the necessary works and keeping them in efficient and satisfactory operation.

Briefly, my recommendations are as follows:

1. That Orange, Montclair and East Orange unite in the construction and maintenance of a sewage purification plant at the site located partly in Bloomfield and partly in Belleville.

2. That the plant consists of grit chambers, Imhoff tanks, sprinkling filters, secondary Imhoff tanks and a sterilizing plant, costing, for construction, about $1,125,000.00, and for operation, excluding interest and sinking fund charges, about $22,500.00, and including these items about $95,000.00 per year.

3. That an arrangement be made by the three cities to perfect a joint administrative commission which shall have charge of the construction and operation of the works, and shall also have jurisdiction over the maintenance, cleaning and operation of the sewers of the three towns, including the main sewer leading to the disposal works.

Further, it is my judgment that there will be no difficulty
4 in building and operating the plant recommended in such a manner that it will not produce disagreeable odors at the plant, or in its vicinity, or along the Yantecaw River Valley; or cause the Yantecaw River to be less desirable, at any time, for any

use to which it can now be put; or in any measureable degree increase the height of floods in the river.

The data upon which these recommendations are based will be found in the following pages.

General Description of the Territory under Consideration.

Orange, Montclair and East Orange lie on elevated ground from two to four miles west of the Passaic River, and to the north and west of Newark. Orange lies to the south of, and adjoins, Montclair, and East Orange to the east of and adjoining Orange.

Montclair has the largest area, about 6.1 square miles, but the smallest population of the three. The lowest ground in Montclair is near Bellevue Avenue, and is about 170 feet above sea level, in the branch of the Yantecaw River. The highest ground is on the mountain top, to the west, which is nearly 700 feet above sea level. Practically all the built up portion of the town lies lower than 400 feet above sea level, and the larger part between 250 and 300 feet. All the sewage from the town can be collected in sewers discharging by gravity to one suitably located point for treatment.

East Orange has an area of 3.91 square miles. The lowest land, which is near Grove Street at the northern end of the town, lies about 110 feet above sea level, and the highest, which is on Prospect Street between Park and Springdale Avenues lies about 190 feet above sea level. The sewage from East Orange can all be collected and delivered by gravity to a point near Second River convenient for connection with a trunk sewer laid to take the sewage from Orange and Montclair.

Orange lies to the west of and higher than East Orange, and its sewage is now brought down to Second River and discharged through the Union outfall sewers into the Passaic River.

The above brief description of the sewerage possibilities of these three communities is given to form a basis of the investigations for a joint disposal proposition. If any significant portion of the sewage of either of the three could not be delivered to a common point of outfall, for collection and subsequent conveyance to the disposal works, without pumping then the advantages of joint action would be less desirable. As it is, the sewage of all can be taken down the valleys of either the Second or Yantecaw Rivers without excessiveiy heavy expense for the construction of the necessary sewers.

In the project which is recommended for adoption it is proposed to construct a new sewer, paralleling the present Union outfall sewer, (which serves Orange, Montclair and Bloomfield), from the junction of the sewer from Montclair to the site of the proposed disposal works in Belleville. This new sewer would be laid on a flatter, but self-cleansing gradient than the existing sewer, in order to deliver the sewage to the works at a high enough elevation to properly carry out the required processes. No pumping would be required to deliver the sewage from the three cities to the disposal works. The cost of the new sewer is included in the estimate of the cost of constructing the disposal works. The cost of the sewer from East Orange to con-

nect with the main outfall sewer is not included, as sufficient data were not at hand, on which to base an estimate.

6 Existing Sewerage Works and Character of the Sewage.

The sewers of Orange, Montclair and East Orange are all on the separate system, that is, they receive only sewage to the exclusion of rain water. A considerable amount of ground water, however, works into the sewers, and this will have to be taken care of at the disposal works.

The sewers of all the cities in this district have good slopes so that velocity of flow is great enough to keep them free from deposits.

The most distant buildings from which sewage will be conveyed to the point where the sewers from Orange and Montclair join is not more than four miles away from the junction, and with the velocities of flow that prevail sewage will reach this point in less than two hours after entering the sewers at the house connections. The sewage, therefore, will be fresh, not having had time in transit for the organic matter in it to begin to putrefy. So far as I have been able to find out, no offensive trades wastes enter the sewers in significant amounts.

To ascertain the actual condition of the sewage I have had samples collected for examination at a manhole on the joint sewer just above the tidal tank and these, together with the absence of odor at this point, where the sewage is violently agitated by falling into the manhole, confirm the conclusion that the sewage to be treated will not be in a putrescent condition when it reaches the plant. This will greatly simplify the problem of its purification.

At the present time the sewage of Orange, Montclair and Bloomfield is disposed of through the Union Outlet sewer extending down the valley of Second River, to the Passaic River. The Branch sewers

7 from Orange, and from Montclair and Bloomfield, (which use the same sewer) are each 24 inches in diameter. Below the junction of these the sewer is egg-shaped, 2 feet, 4 inches wide and 3 feet, 10 inches high, there being, however, some 36-inch and some 30-inch stretches, including river crossings. From the tank to the outlet into the Passaic, a distance of some 3,800 feet, it is of cast iron 48 inches in diameter.

Quantity of Sewage to be Provided for.

Based upon the available data, the sewage originating in the three cities, which are of the same nature as to occupancy and commercial interests, should average about 100 gallons per capita.

The sewage does not flow through the sewers at a uniform rate throughout the twenty-four hours, or at the same rate on different days; from general experience it is found that the least flow is about 2 or 3 o'clock in the morning, increasing to a maximum about 9 to 10 o'clock in the morning, then decreasing towards noon and rising again about 2 in the afternoon, and that the maximum rate of flow to be expected will be from one and a half to two times the average rate of flow. Since there will be no storm water to be taken care of

in the system the works can be designed to accommodate the quantities of sewage that will result from the populations given in Table I, with an additional allowance to provide for the ground water entering the sewers.

Daily gaugings of the depth of flow in the sewers from Orange, and from Montclair and Bloomfield, have been kept since 1894, for the purpose of apportioning the cost of maintenance of these sewers among the cities using them, payment being made on the basis of relative use. A study of these gaugings which were placed at my disposal by Mr. Crane, City Engineer, of Orange, N. J., shows that a very considerable percentage of the total flow is ground water which leaks into the sewers. An analysis of these records indicates
8 that the ground water flow varies from season to season through a wide range. For instance, during the first 7 months of the year 1908 both sewers ran entirely full, for the entire period, and at times were much over-taxed. During the past 8 months of 1911, however, they have run about 2/3 full most of the time, and entirely full for about a month. As nearly as I can estimate the minimum ground water flows in these two sewers together has been about 4,000,000 gallons per day and the maximum in excess of 7,000,000 gallons, or, reduced to leakage per square mile of sewered area, the figures would be about 280,000 gallons for the smallest rate and over 490,000 gallons per square mile per day for the greatest. Adjusting these figures to the cities of Orange, Montclair and East Orange the quantities of ground water to be taken care of at the disposal works would be about 3,500,000 gallons daily for the ordinary dry weather flow, and 6,000,000 gallons daily for wet weather flow, the latter rate persisting for possibly half a year at a time. For shorter times rates reaching nearly 9,000,000 gallons daily are likely to be reached.

The past, present and estimated future populations of Orange, Montclair and East Orange are given in Table I.

TABLE I.

Populations.

City.	Areas. Sq. miles.	Populations. 1900. U. S. Census.	1910. U. S. Census.	Estimated For 1925.	Estimated For 1940.
Orange	2.22	24,141	29,630	45,000	60,000
Montclair	6.10	13,962	21,550	35,000	50,000
East Orange.....	3.91	21,506	34,371	53,000	70,980
Totals.....	12.23	59,609	85,551	133,000	180,380

Disposal works should be built of sufficient capacity to pro-
9 vide for some years in advance of the present, so as not to require extension immediately. On the other hand, it would not be economical, either as to cost of construction or efficient operation to build them large enough to serve populations that will not

be reached for more than a generation. In my judgment works large enough to take care of the population that may be expected by 1925 will be as large as should be built at present, as this will give sufficient margin of capacity to permit extensions to be made, should the population increase more rapidly than estimated above, in ample time to provide for the increased population. On the other hand, the main sewer leading to the works, which would be costly to duplicate, should be large enough to take care of the maximum rate of flow to be expected by 1940.

Based on the populations given in Table I., and on the assumption that, on account of the considerable time that some of the sewage will require to reach the disposal works, the maximum rate of sewage flow will be 50 per cent. in excess of the average rate, the maximum quantities of sewage that would reach the disposal works, in 1940, from the three cities, including ground water, would be as given in Table II.

TABLE II.

Estimated Maximum Rate at which Sewage Will Reach the Disposal Works in 1940.

Million Gallons Daily.

City.	Constituent parts of sewage. House sewage (150 gallons per capita).	Ground water 700,000 gallons per sq. mile daily.	Trade wastes.	Total maximum rate of sewage flow.
Orange	9.00	1.82	0.85	11.67
Montclair	7.50	4.31	0.01	11.81
East Orange	10.65	2.74	0.09	13.48
Totals	27.15	8.87	.95	36.96

10 For the average conditions of flow that may be expected in 1925, the figures would be given in Table III.

TABLE III.

Estimated Average Rate at which Sewage Will Reach the Disposal Works in 1925.

Million Gallons Daily.

City.	Constituent parts of sewage. House sewage (100 gallons per capita).	Ground water 280,000 gallons per square mile.	Trade wastes.	Total.
Orange	4.50	.62	.26	5.38
Montclair	3.50	1.70	.01	5.21
East Orange	5.30	1.09	.03	6.42
Totals	13.30	3.41	.30	17.01

On the above assumptions, therefore, the capacities of the principal divisions of the works should be able to accommodate the quantities of sewage estimated as follows:

The main outfall sewer to the disposal plant, and the main outlet pipe from the works, the maximum rate of sewage flow from 181,000 people, amounting, including ground water flow, to 37,000,000 gallons per day, the sewer to run three-fourths full with this quantity of sewage.

The disposal works, the average rate of sewage flow from 133,000 people, amounting, including ground water, to 17,000,000 gallons per day, the works being so laid out as to permit of extensions, when necessary, to provide for receiving the sewage from a population of 181,000 people, amounting, including ground water, to an average rate of flow of 23,000,000 gallons daily.

Although the average rate of flow of the sewage in 1925
11 will be about 17,000,000 gallons daily there will be times when the rate will reach about 23,000,000 gallons and the works will have to take care of it as it comes. By proportioning the plant properly the increased rate necessary for a few hours daily will not injuriously affect the character of the effluent, as the processes to be used are flexible enough to secure satisfactory results within these limits.

Methods of Disposal of Sewage.

Sewage from cities like Orange, Montclair and East Orange, consists of water carrying away, partly in suspension and partly in solution, the wastes from the houses and buildings of the people. About 999 parts out of a thousand, by weight, of the sewage, are clean water, and it is the organic portion of the one part, (which latter is about half mineral and half organic matter) which, by decomposition and putrefaction gives rise to foul odors and nuisances. The construction of purification works, of considerable cost, therefore, is made necessary by a relatively small amount of putrescible organic matter in a very large amount of water, and the problem is one of removing this small amount of organic matter from the water, or destroying it, or changing it before putrefaction sets in to a form in which it will not subsequently become offensive.

Generally speaking the process, for economical and practical reasons, must be done in two stages, the first being to remove quickly, before decomposition sets in, by subsidence, screening, filtering, or combinations of these, as large a part of the suspended matters from the sewage as advisable under the condition prevailing. These suspended matters consist of silt, sand, coagulated clay, fibres and pieces of paper, rags wood and resistant solids, particles of excrement, scraps of meat, vegetables and other refuse from houses, markets, and factories.

12 The second stage in the treatment is to oxidize or destroy those portions of the wastes in solution, and of the solids in suspension, particularly those of an organic origin, too small to be removed by the processes available for the first stage of the treatment, and to destroy and eliminate the bacteria which accompany the

organic matter in the sewage and which pass through the first stage of treatment without being reduced materially in numbers.

The first stage of the treatment is essentially mechanical, as the work must be done quickly in order to keep the sewage fresh and inodorous when it undergoes the second stage of treatment, which is essentially chemical, although the resulting chemical changes are largely brought about by living organisms.

For the first stage two operations are necessary, the first being to separate the suspended matters from the liquid sewage and the second to dispose of these suspended particles after they have been removed. The first stage is necessary for the reason that if not carried out the second stage would fail by the clogging of the works, with resultant putrefaction and nuisances which might necessitate the reconstruction of the works. When the first stage is efficient the second is easy of consummation; and the more efficient the first the greater the success and efficiency of the second.

The extent to which the purification of the sewage must be carried in any case depends upon local conditions. When an outlet can be had to the open sea, or to a great river whose flow is large enough to disperse, dilute, and purify it, no treatment is necessary save perhaps screening and the removal of sand. Where the outlet is into a small stream running through pasture lands, or serving as a water supply or ice supply for inhabitants in the vicinity, the sewage must be purified to as high a degree, and to as uniform a quality, as possible of attainment.

13 The processes available for the first stage, stated in the order of their efficiency in the removal of suspended matters from the sewage are: coarse screens; fine screens; ordinary settling basins, operated with or without chemicals; slate beds; specialy designed settling basins (such as the Dortmund and Imhoff tanks); and especially designed, rapidly operated filters in connection with special forms of settling basins.

Coarse screens will remove only large particles and floating matters. Fine screens will remove a somewhat larger percentage of such matters, but fail to intercept the finest particles of silt and mud in suspension. The particles removed by screens are disposed of by burning or burying.

Ordinary settling basins, when well designed, will largely remove the suspended matters, which require frequent removal to avoid nuisances. The sludge resulting from deposition in such basins is great in amount and difficult to dispose of owing to its large percentage of water and the slowness with which it dries out. Its disposition is effected, when no chemicals are used, by draining it off into lagoons to dry out, and then digging it out and hauling it away; or plowing it into the ground where this is feasible, or discharging it into tanks, or trenches, to "work" or digest, and after reaching a proper condition, digging it out and hauling it away; or, where chemicals are used, passing it through so-called filter presses to squeeze out the water, using the resulting cakes of pressed sludge for filling low ground, or otherwise disposing of it.

Mr. J. W. Dibden, of London, has in recent years introduced in

many places special settling basins containing layers of slate arranged to facilitate the deposition of the solids and their digestion in an inodorous manner. The efficiency of such beds, so far as the effluent sewage is concerned, is about the same as of septic
14 tanks, and its disposal involves about the same problems. The humus, or sludge, however, from such beds, when these are properly designed and operated, is inodorous and smaller in quantity than from ordinary settling basins. The cost of the beds for many locations, however, would be great in comparison with other processes producing under ordinary conditions equally good or better effluents.

Specially designed settling basins, such as the Imhoff tank, so-called in honor of Dr. Karl Imhoff, of Essen, who perfected it, will remove as large a percentage of the suspended matters from the sewage as can be economically taken out by subsidence, and at the same time reduce these deposited matters to an inoffensive condition of smaller volume than deposits from similar sewage in ordinary settling basins; further, the condition of the sewage itself as to freshness is not altered while passing through the tanks.

Specially designed rapidly operated filters, in connection with specially designed settling basins, will remove practically all of the suspended matters, and when operated in connection with chemicals, a portion of the dissolved organic and mineral matters, and give a clear effluent, and one that could be discharged into relatively smaller streams, without fear of nuisance, than the other preliminary processes. The matters removed from the sewage by the filters would be passed back to the settling tanks to be digested with the matters deposited from the sewage therein before reaching the filters.

The removal of the deposits from the specially designed settling basins, in these two last mentioned processes, would be accomplished by emptying it from the bottoms of the tanks upon shallow beds of fine gravel where the water would drain out and permit the sludge to dry out. The dried sludge would be removed and disposed of on low ground in the vicinity, or wherever convenient. Sludge removed from such tanks dries readily. Its water content is much less
15 than that of sludge removed from ordinary settling basins, and when discharged upon beds for drying is charged with inodorous gases, evolved during its digestion in the tanks, which makes it light and porous, permitting the water to drain out readily.

Other preliminary processes for the removal of the suspended matters, being modifications and combination of the above, are in use at various places at home and abroad, but the methods outlined elucidate in a broad way the principles underlying all the methods in practical operation.

Among the modifications may be mentioned one wherein the sewage is retained in the settling basins for a long enough time to allow putrefaction to begin, with the aim of thereby reducing the quantity of sludge to be handled, by causing some of the solids to go into solution and be carried out of the tank with the sewage. Tanks of this sort are called septic tanks and a few years ago were introduced extensively. Owing to the difficulty of disposing of the effluent from the tanks, which generally smells badly, their use is now limited

to special situations and conditions. Another modification is the use of coarse grained filters, operated at a rather high rate, to serve the purpose of very fine screens. Such filters, however, are usually short lived, unless elaborate provisions are made for keeping them cleaned, otherwise when they become clogged the filtering materials require removal and replacement.

It will be seen, therefore, that a decision as to the proper method of preparatory treatment to be adopted will depend upon the method of secondary treatment necessary, and this must be adjusted to give the character of effluent desired from the plant.

The more prominent and widely used forms of secondary treatment are:

16 1. The treatment of the sewage with chemicals which assist in producing a relatively rapid and extensive deposition of the solids in suspension, and the removal of about half of the organic matters in solution.

2. The disposal of the sewage by using it to irrigate large tracts of land, either for raising crops of various sorts, or for getting rid of it. This process requires a large area of land, and has the disadvantage that during rainy weather, when the ground is soaked with water, the sewage can not be taken care of so readily, and ponding is apt to result.

3. Passing the sewage through contact beds. These are tanks containing relatively coarse granular materials, through which the sewage is passed in a manner to bring it in contact with the air entrained in the bed and allowing it to stand for a certain length of time to produce the necessary oxidation and bacterial action; the sewage is then emptied out, either to a second set of similar beds or to its final place of discharge, depending on the degree of purification desired. Such beds, when properly designed and operated, are inodorous, produce excellent results, giving an effluent acceptably clear and oxidized to a condition of stability, that is: rendered non-putrefactive. Generally, however, such beds eventually partially clog up with the sewage matters deposited therein and the filtering matters have to be removed and new ones put in their place. The relative permanency of such beds depends upon the fineness of the materials and the extent to which the preliminary process used removes the suspended matters.

4. Spraying the sewage over deep beds of coarse granular materials. Such beds are called sprinkling filters. Sprinkling filters, when properly designed and operated, will oxidize the organic
17 matters in solution in the sewage, as well as the fine particles in suspension to a stable or non-putrescible condition. The effluent from such filters, however, is not clear, as the clay, silt, etc., is not retained by the coarse-grained materials forming the bed. Their life depends upon their ability to unload or discharge the matters temporarily retained therein after their conversion to a non-putrescible condition. Generally, therefore, further treatment is necessary to remove the suspended matters from the effluent, and this may be done by subsidence, by passing it through contact beds, or by filtration through specially designed filters, the water used in

washing which would be discharged back into the raw sewage entering the preliminary treatment works. Contact beds for this purpose offer the disadvantage of gradual loss of capacity by clogging, and of changing unfavorably the chemical character of the effluent from the sprinkling filters, when this has to be discharged into streams and ponds.

5. Filtration of the sewage through specially prepared beds of sand by applying it to the filters intermittently in doses no larger than the character of the sewage and construction of the beds will permit to secure the oxidation of the organic matter and removal of the bacteria. When properly designed and built such filters will purify the sewage to a very high degree, yielding an effluent clear, non-putrescible and freed from a very large percentage of the bacteria. The necessary works, however, are generally expensive to build, particularly when the beds have to be artificially constructed of sand brought from a distance; further, they must be operated with intelligence to keep them in an active and efficient condition.

18 In some cases it is necessary to carry the purification to still greater lengths than can practically be obtained by any of the above mentioned processes, and in such cases the effluent from the works can be sterilized, after being rendered clear and non-putrescent, by the use of some sterilizing agent, such as hypochlorite of lime or soda, or by the use of ozone, which can be prepared from the air by electrical treatment.

Available Sites for Disposal Works.

The method of disposal that will be best suited to local conditions will depend upon the sites available for the works.

After looking over the situation with much care I have found but two localities where works could be located. These are:

1. The site selected and now controlled by the cities interested, which is located in the northwest corner of the Town of Belleville, and northeast corner of Bloomfield.

2. One of two sites on the meadows of the Hackensack River.

The second mentioned sites, while suitable for the construction of the works, are far away and lie beyond the hill which separates the Passaic River Valley from the Hackensack Meadows and to utilize one of these would necessitate building and maintaining a pumping station to elevate the sewage over the hill; and to utilize the other, resorting to pumping, or to the use of an inverted siphon to get the sewage over the 60-foot hill east of the Passaic River, in addition to constructing several miles of large trunk sewer, for either site. The cost of pumping the sewage, without interest, depreciation and sinking fund charges on the cost of the sewer and pumping station, would, for the lower site, be upwards of $40,000.00

19 per year, which would represent, at 5% interest, a capital investment of $800,000.00, and would make the project less desirable from a financial standpoint than the Belleville site, as practically the same character of effluent would be required from the works in either case in order to avoid, in the case of the meadow site, the pollution of the Hackensack River and Newark Bay. The use

of the upper meadow site, with an inverted siphon under the Passaic, while possibly practicable, would involve much expense for construction, and some difficulties in operation, which can be avoided at the Belleville site.

This being the case the problem in hand becomes one of determining the character of effluent required from works situated at the Belleville site, and the conditions that must be fulfilled with respect to the avoidance of nuisances locally.

Character of Effluent Required.

The tract of land chosen for the location of the disposal works lies along the south bank of the Yanteeaw, or Third River, the effluent from the proposed plant must be discharged into this stream. In order to design the works, therefore, it will be necessary to know the conditions of flow that prevail in the stream at different seasons, the topographical, meteorological and geological features of the district, the character of the country through which the stream flows as to occupation for residences and manufactories and the probabilities for future growth and improvement for these uses that would be affected by the construction of the works.

Immediately below the proposed site is a shallow pond some 2,000 feet long formed by a dam about 2,300 feet up stream from Harrison Street. A little over a mile further down is another dam, the back water extending up to within about a mile of the first mentioned pond. Three-fourths of a mile below the second dam is a third forming a pond about 2,000 feet long, furnishing power to a paper mill, and three-fourths of a mile below this is a fourth, which supplies two mills, the larger of which is a bleaching mill. The back water from this pond reached up to within half a mile of the third dam. There are no other dams on the stream before its junction with the Passaic opposite Lundhurst. Between the ponds formed by these dams the stream is in some places swift and others sluggish, winding about the valley through a shallow channel with low banks bordered by grass lands, lawns and fields, and some marsh lands. Generally speaking the banks are covered with underbrush and the channel more or less obstructed with growths of various sorts although some portions have been straightened and cleaned out.

For about half a mile below the proposed works to below Nutley, and Franklin, the stream flows through a well built up suburban residential district containing many fine properties, to some of which the creek in a clean wholesome condition is a valuable asset while in an unclean condition would be not only a nuisance but a damage of serious proportions. The water of the creek is not, and should not be used for a domestic water supply, whether the proposed sewerage works are built or not, and should not, whether it is now so used or not, be taken as an ice supply for the people of the vicinity, so that for these purposes the effluent from the proposed works, if of a high enough purity, would not damage the stream.

There are clear indications that in the future the district through which the stream runs will continue to improve, and that the popu-

lation resident in the valley and surrounding hills will increase, probably more rapidly than it has in the past.

21 A comparison of the sewage flow from 181,000 people (the estimated population 1940) to the estimated natural flow of the stream, which has a watershed area of about 8.6 square miles above the site of the proposed works, is given in Table IV.

TABLE IV.

	Estimated flow of Yantecaw River, in million gallons daily.	Average rate of sewage flow in 1940, in million gallons daily.
Minimum daily flow of river	0.7	23
Minimum monthly flow of river	1.0	23
Flows for average year:		
Driest month	3.8	23
2nd driest month	4.0	23
3rd " "	4.2	23
4th " "	4.7	23
5th " "	6.6	23
6th " "	8.0	23
7th " "	9.5	23
8th " "	11.7	23
9th " "	13.6	23
10th " "	13.9	23
11th " "	14.2	23
Wettest month	14.3	23
Frequent flood flow	200.0	23
Large flood flow	430.0	23
Maximum flood flow	1200.0	23

It is evident, from this Table, that the character of the effluent from the plant must be of a high order, as the sewage flow, even when the plant is first put in operation, will average greater in amount than the average natural stream flow throughout practically the entire year.

During ordinary floods, which occur with frequency, the sewage flow will not have any noticeable effect towards raising the flood heights, and this effect will diminish with the intensity of the floods.

If the sewage is purified to a high enough degree, however, the effect of its discharge into the stream will be beneficial by causing a more copious and uniform flow throughout the year. All the sewage reaching the works, therefore, would have to be purified to a very high degree.

22 The water of the Yantecaw River is now somewhat discolored and polluted by manufacturing wastes, but is not very offensive, as no great quantity of sewage enters it.

Its velocity, however, is rather sluggish throughout most of its length, owing to the presence of the dams above mentioned, which

have been in existence for many years for furnishing power and for other uses.

Summing up, it can be seen that to fulfill the necessary conditions the effluent from the proposed works must be free from suspended matters, clear, free from odors, free from matters in solution that would putrify and cause disagreeable odors, and free from constituents that would cause troublesome growths in the stream and ponds, especially during times when the water would naturally be clear. It is also necessary that the removal of the bacteria from the effluent should be great enough not to cause added pollution to the stream, particularly with respect to those forms which contribute to, or cause, water borne diseases. In other words, the effluent from the plant should always be in as good or better condition than the natural flow of the stream.

Other conditions, however, must also be fulfilled by the works and these relate mainly to the simplicity of the plant, its reliability and its flexibility in dealing with varying quantities of sewage flow without diminution of efficiency, and without causing offensive odors or other nuisances at the works, or in the stream below the works.

Type of Plant Best Suited to the Site Selected.

From surveys which have been made by Mr. Crane, City Engineer, of Orange, N. J., it appears that the invert of the main sewer can be placed at an elevation of 89.5 feet above sea level at the disposal works. The elevation of the surface of the sewage in the
23 sewer, at the works, at minimum flow, will be, therefore, 91.5 feet above sea level. As the water in the Yantecaw River at ordinary stages is 72 feet, the available head for passing the sewage through the plant will be 19.5 feet, which is sufficient for the purpose.

In the matter of purification it is best to consider first the most suitable method of final disposal and then select the method of preparatory treatment that will be best adapted to prepare the sewage for final treatment.

Broad irrigation is out of the question as there is not enough land available for the purpose. It would probably require about 2½ square miles of land, with soil of the kind common in that locality, to properly assimilate the sewage, and the cost of maintenance would be greater than any possible revenues that could be had from crops that could be successfully grown on the area.

Chemical precipitation would be unsuitable, unless followed by, or combined with other processes, as the effluent, although clear, would still contain enough organic matter to putrefy and cause a nuisance.

Contact beds, particularly if used in series so that the effluent from one set of beds would pass through a second set before discharged into the stream, where the method can be used, will give a stable effluent of good purity and the works can be maintained without nuisance. In order to use this method successfully the sewage must be delivered to the works at a high enough elevation to permit of the construction of the works, using a sufficient depth of filtering

materials to effect the proper purification, and allowing sufficient extra head to operate the mechanisms necessary to discharge the sewage into each set of beds and permit them to drain out again before the next filling. A further requirement is that provisions must be made in the maintenance charges for renewing the filtering materials at greater or lesser intervals of time, owing to the retention therein of the accumulating, unchangeable mineral matters. Double contact beds could not be built at the available site without pumping all the sewage up to a higher elevation than that to which it can be delivered by gravity, and the cost of construction and annual cost of operation would be greater than for sprinkling filters.

Sprinkling filters can be built at the site selected, and will give an effluent that will not subsequently putrefy. It will, however, in order to render it clear, require further treatment to remove the suspended matter, and also may require sterilization, as the bacterial purification of such filters is not high. For rendering the effluent from the sprinkling filters clear two plans are available, one being subsidence in settling basins and the other filtration through specially constructed rapidly operated filters. The filters would produce a brighter effluent than the basins, but at greater cost for construction and operation. Furthermore, at the site selected there would hardly be head enough available for their operation without pumping.

Settling basins of the Imhoff type, if properly designed for this work, would give excellent results in the final clarification of the effluent, particularly if operated in connection with chemicals to assist in hastening the work. Recent experience in Germany has shown that chemicals can be used in this connection without interfering with the efficiency of the tanks in sludge digestion.

The combination of secondary processes to produce a clear, nonputrefactive effluent, therefore, would be sprinkling filters followed by subsidence in specially designed Imhoff tanks.

For the preparatory process there is not sufficient head available to use either coarse grained filters or slate beds. Ordinary settling basins could be used, but the removal and separate treatment of the sludge depositing upon the bottom would involve difficulties and nuisances. Imhoff tanks appear to be the only available form of tanks that can be adapted to the location. These will remove enough of the suspended matter from the sewage to permit of satisfactory results with the sprinkling filters, and they solve the question of sludge reduction and removal more satisfactorily than any other process with which I am familiar. The sewage flowing to the tanks will need no further treatment than to pass through coarse screen bars, placed about 2 inches apart, and thence through a shallow, widened section of the sewer channel in which the velocity of flow will be reduced to about 1 foot per second. This channel should be long enough to give time for the silt and sand, which enters the sewers through the perforations in the manhole covers, to settle down upon the bottom.

To secure the necessary bacterial purification of the effluent, from the secondary settling basin, before discharge into the Yantzaw

River, a solution of hypochlorite of lime, or some other cheap form of sterilizer may be used.

The arrangements for using the sterilizing solution should be planned so that it could also be introduced into the effluent from the first Imhoff tank before it reaches the sprinkling filters, if desired, to prevent troublesome growths in the filters. These have occurred in certain plants, and have been cleared out and their return prevented in this manner.

Briefly, then, the type of plant best adapted to secure the quality of effluent necessary would consist of:

1. Coarse screens, about 2 inches apart.

2. Deposit chamber for silt and sand, in which the velocity of flow would be reduced to about 1 foot per second, the chambers to be 75 to 100 feet long, to secure the deposition of sand and
26 silt. This can be provided for by having three such chambers, so that one or all could be used, depending upon the volume of sewage flow and character of the sewage.

3. A set of Imhoff tanks for the removal of the suspended matters and the digestion of the sludge, the settling compartment of the tanks to have sufficient capacity to hold three hours' flow of sewage at the average rate, and the sludge compartment large enough to hold six months' accumulations of sludge. There would be 12 tanks, each about 27 feet deep and 100 feet long, in the direction of flow, holding a volume of about 4,420,000 gallons, and covering, including the channels between the beds about 1.15 acres.

4. Sprinkling filters to oxidize the organic matter in the effluent from the tanks to a stable, or non-putrefactive condition. These should have sufficient area to handle the average flow of sewage at a rate not greater than 2,000,000 gallons per acre of filter surface, per day, and could be arranged in two units, covering, including space for chambers, about 8 acres, or a tract about 500 feet wide and 700 feet long. The sewage would be sprayed over the beds from dosing tanks operating under heads varying from 2½ to 6 feet. The beds would be built up to a depth of about 8 feet of stones varying from 1½ to 2½ inches in diameter.

5. A second set of Imhoff tanks, to allow of the subsidence of the suspended matters from the effluent of the sprinkling filters, to hold about two hours' flow of sewage and to be operated with or without the use of chemicals to aid the settlement, depending upon the character of the sewage being treated, and being constructed with sludge chambers holding about 10 days' accumulations of sludge, the de-
posits in which would be pumped back to the first set of
27 Imhoff tanks intermittently, as required. These secondary tanks would be about 15 feet deep and 95 feet long in the direction of flow, arranged in 12 units having a total volume of about 2,000,000 gallons and covering an area of about 0.75 acre.

6. A chemical dosing house in which to prepare the sterilizing and precipitating chemical solutions, should it be necessary to use either one or the other or both together. The piping arrangements from this house should permit the discharge of any of these solutions, either into the sewage as it goes upon the sprinkling filters, or

into the second set of Imhoff tanks or into the effluent from these tanks before it goes into the river.

7. With the primary Imhoff tanks will also have to be arranged sludge beds for draining the water out of the sludge, and places for disposing of the sludge thus removed. The sludge beds will require an area of about one acre and should be well underdrained and covered with a surface layer of fine material.

The arrangement of the Disposal Plant, of course, is subject to modification after detailed surveys and borings have been made and after sufficient study has been given to the subject to work out the most economical plan.

Method of Operating the Plant and Results of Operation.

As before stated, the sewage will arrive at the plant in a fresh condition and will consist of ordinary town sewage diluted with clean ground water. The underlying principle in the design of the plant must be to keep the sewage in a fresh condition while separating from it the suspended matter and changing the dissolved organic contents into a non-putrescible condition. After this part
28 of the process is completed the matters temporarily retained in the sprinkling filters (which from time to time are washed out and cause the effluent to be somewhat turbid) must be separated therefrom and disposed of; and finally, if necessary, the escaping clear water must be sterilized. Further, the deposits that take place in the Imhoff tanks must be disposed of in a satisfactory manner, and there must be no odors about the place that would cause offense to people living in the neighborhood of the plant, or along the stream below.

Screens.

The screens for the plant should consist of iron bars placed in the inlet channel to the plant, about 2 inches apart and sloping at an angle of about 20° to the horizontal. These are intended to intercept and permit the removal of tin cans, bottles, boxes, boards, bricks and other large floating or heavy matters which would obstruct the slots, or the sludge outlet pipes from the Imhoff tanks. These matters removed from the fresh sewage will be small in amount, and can be readily disposed of without nuisance by burying, burning or other commonly used methods.

A photographic view of the usual type of screens employed for this purpose is shown in Figure 5.

There should be no odor whatever about this part of the works if the superintendent takes the trouble to keep the place clean.

Grit Chambers.

A velocity of flow through the grit chamber of 1 foot per second will deposit the sand, but none of the organic matter; this latter will all go to the tanks for subsidence and decomposition. Ordinarily there will be no grit or sand in the sewage. After heavy rains

a certain amount may wash in through the perforations in
29 the manhole covers in the streets of the town. This will be caught in the grit chambers and can be removed, as necessary, without nuisance. It will not give offense when dumped on the low ground below the plant, and after draining out and being rained on a few times will purify itself of the small amount of organic matter it contains, and can then be used for renewing the top surface of the sludge draining beds for the Imhoff tanks.

Imhoff Tanks.

The Imhoff tanks should be designed to give the sewage about three hours to deposit its suspended matters, and with sufficient room in the sludge chamber beneath to hold about six months' accumulations of sludge.

The plant would include 12 of these tanks. Each would consist of a settling chamber, with a sludge chamber beneath it, so arranged that the solids which are deposited in the settling chamber will slide down through a slot in the sloping floor to the sludge chamber beneath, the slot being arranged, by lapping one edge over the other, so that while the solids can pass down the gases that form when the solids decompose in the lower chamber can not rise up into the fresh sewage passing through the settling compartment over head. Scum-boards and baffleboards would be placed in each settling compartment to intercept the floating matters and secure as uniform and perfect subsidence as possible. Each tank would be arranged with inlet and outlet pipes and necessary control gates so that the sewage could be passed through the tank from either end, at will, and fill the sludge chambers uniformly. From each sludge compartment a valve-controlled emptying pipe would permit emptying the sludge upon the drying beds, as desired. Perforated water
30 pipes would also be installed in the sludge chambers, at the bottom and along the sides to assist in loosening up the sludge before emptying and to permit its agitation, if required, and a connection would be made to the sludge emptying pipe so that after emptying a tank all the sludge left in the pipe after closing the valve could be blown back into the tank and thus leave the pipe full of clean water.

The tanks should be built of concrete with very smooth surfaces and steep slopes and all the channels leading to and from them should be open and smooth so as to permit of keeping them perfectly clean and free from deposits.

In the construction of the tanks ample room should be provided for the floating matters that rise up from the sludge compartment and form a crust, or scum, over the surface.

Tanks of this type can be made either circular or rectangular in form, as best suits local conditions of economical construction, and are usually about 30 feet in depth, with conical or pyramidal shaped bottoms in the sludge compartment to keep the sludge together during its rotting. A general view of the tanks at Essen-North receiving the sewage from 180,000 people is shown in Figure 1.

During operation the sewage passes through the tank in a continuous stream, which is not interrupted thereafter, the solids in suspension settling to the bottom and sliding through the slot to the sludge chamber below. As great a proportion of the solids as can be removed economically by subsidence will drop to the bottom compartment in from one to three hours, depending upon the nature of the sewage. In some of the plants in successful operation only one hour's subsidence is necessary, while in others a longer time gives better results. Generally speaking, the proportion of the solids that can be removed from ordinary sewage, by subsidence, in periods longer than 2 hours, is so small that it does not pay to expend the necessary capital to secure the slightly higher percentage re-
31 moval, particularly as the processes adapted for further treatment can receive and treat one effluent as well as the other; and the more quickly the sewage can be passed through the settling tanks, to produce an effluent suitable for the second treatment, the less the risk of having offensive conditions about the plant.

The solids which settle out of the sewage in transit through the settling tank collect in the bottom of the sludge compartment and undergo decomposition, until reduced to a slimy black material resembling peat mud. It takes several months for this process to be completed; and the tanks, therefore, require sufficient sludge space for this to occur. Generally no sludge is drawn out of the tanks, after first being put in operation, for three or four months, or longer, depending on the rapidity and completeness with which its decomposition has gone on. After the tanks have been in operation for several months, however, the sludge is removed at more or less frequent intervals to make room for the new materials continually being deposited. The times of drawing out sludge can be accommodated to weather conditions, the sludge being allowed to accumulate, during very cold, or wet, weather until favorable conditions occur to facilitate its drying.

During the decomposition of the sludge various gases are evolved, the principal of which are carbon dioxide and marsh gases, the same that can be seen coming up through the water in swampy places where leaves, grasses, roots and other organic matters decay under the water. These gases have no appreciable odor and are liberated in too small amounts from the tanks to be detected in the air after liberation from the surface of the lisuid. The absence of the odor of sulphuretted hydrogen, which smells like rotten eggs, and is usually the principal source of nuisances from decomposing organic matter, whether garbage, sewage or other similar mat-
32 ters, is one of the marked characteristics of the decomposition which takes place in these deep settling tanks. No explanation has yet been given of the phenomenon, but that it is a fact can be attested to by all who have visited the many such tanks in operation in the Emscher Valley where they were first built and are now being introduced in increasing numbers.

It has been suggested that the absence of the odor of sulphuretted hydrogen might be due to the presence of iron, in the sewages being treated in the Emscher district, with which the sulphuretted hydro-

gen would combine and thus not be liberated as a gas, but the fact is that some of the tanks are receiving sewage of a purely domestic nature, which show, on analysis no iron, as successfully as others which contain it in large amounts. At the experiment stations established by the Cities of Philadelphia and Chicago the same results have been secured as in the Emscher district in Germany, in this regard, and the sewages treated show on analysis no more iron in solution than average normal American town sewages.

It is to be noted that non-odorous decomposition does not begin at once, but only after the tanks have been in use for two or three months. When a tank is first filled with sewage the sludge chamber, as well as the settling compartmest fills with sewage until it rises up high enough to flow out of the overflow from the tank. The whole sludge chamber is thus filled with sewage which can not get out again, and the organic matter in it, both in suspension and in solution, has to decompose and rot. During this period there may be occasions when more or less odor will be noticeable about the tanks, particularly during hot, humid weather. After this first sewage has once decomposed, however, no further odors come from the tank when in normal operation, and the water in the sludge chamber, above the sludge, is practically clear and non-odorous, and
33 covered with a crust or scum from which the only odor is a faintly tarry smell which can be detected only by turning the scum over with a fork and placing the nose close to it. At least this has been my experience at these works. After a state of equilibrium has been reached no more fresh sewage enters the sludge compartment excepting such quantities as may be required to make up for the volumes of sludge drawn out from time to time.

Owing to the method of constructing the tanks the gases which are evolved in the sludge chamber, in excess of what the liquid in the chambers will dissolve at the prevailing temperatures and pressures where dissociated during decomposition, rise up through the liquid and are deflected by the underside of the sloping bottom of the settling compartment, and issue to the air through the sludge space without passing through the fresh sewage flowing through the settling compartment. This prevents the contamination of the fresh sewage with the rotting particles carried up by the bubbles in the sludge chamber and allows the settled sewage to flow through and out of the tank still in a fresh condition.

Sometimes, particularly after having been in operation but a short time, and when silt and sand are allowed to go into the tanks, the sludge solidifies in the bottom of the sludge chamber and the liberated gases, accumulating thereunder, lift large pieces up which may choke the slot and prevent the entrance of the solids deposited from the fresh sewage. When this occurs it is necessary to draw off some of the partly decomposed sludge and clear the slot; this operation is attended with more or less odor, but is a condition which rarely occurs and which can be prevented by an alert attendant, and, if occurring, can be remedied by simple and effective measures. It does not occur in well designed and properly operated tanks.

The formation of gases in the sludge chamber is of much
34 importance in facilitating the handling and drying of the sludge. As is well known, the quantity of gases water will dissolve, other things being equal, is proportional to the pressure. The gases which are liberated in the bottom of the tank are dissolved under a pressure of about 30 feet of water, or about one atmosphere in addition to the atmospheric pressure. When this water, containing the gases dissolved under this pressure, is brought up to the surface at atmospheric pressure, the gases can no longer be held in solution and are *occluded* in the form of fine bubbles. The ordinary siphon of carbonated water is a familiar example of this phenomenon. These waters are charged with carbonic acid gas under heavy pressure and the water takes the gas in solution. As soon as some of the water is drawn from the siphon the pressure of the gas on the surface of the water in the siphon is reduced, and bubbles form in the water and continue to rise to the surface until equilibrium of pressures and quantities held in solution is again established, when the bubbles cease to form and the water becomes quiet.

This is the case when the liquid sludge is drawn from the bottom of the Imhoff tank. As soon as the sludge valve is opened the weight of the water above the value forces the sludge up through the sludge pipe, the outlet of which is lower than the surface of the water in the chamber, and the sludge flows out of the pipe charged with gases under pressure. When it reaches the air these gas bubbles expand and loosen the sludge up to a spongy porous condition. The mass is sticky, at first, and it apparently stiffens up, on the sludge draining beds, with the spaces formed by the gas bubbles preserved in the form of pores and open spaces. This greatly facilitates the process of drying, allowing the water contained in the liquid sludge to drain out so freely that ordinarily the sludge can be handled with shovels, like moist soil, a few days after being discharged upon the beds.

35 Last July I visited the plant at Recklinghausen, which treats the sewage of 26,000 people, two days after sludge had been discharged upon the beds from one of the tanks, and it was then dried out so that cracks covered the surface; it was shoveled from the beds the next day and wheeled in push-cars to the dump close at hand. I remained about the plant for some time examining the works, the character of the incoming sewage, the effluent from the works, the fresh sludge drawn from the sludge chamber at my request, the partially drained sludge on the sludge beds, the water draining from the sludge beds, the channel that had been receiving this water for several years, and the piles of sludge that had been removed from the beds in the past, and I could not find any odors about the place, except the smell of new mown hay that was being cut in fields several hundred feet away. This plant had been in continuous operation since the Fall of 1905. A photographic view of the Recklinghausen plant is given in Figure 3.

I visited the works when they were being operated under ordinary every day conditions, and not in anticipation of visitors, having gone

there without appointment. My visit was unexpected until I called upon Dr. Imhoff at his office in Essen and asked to be allowed to go down to the plant at once. The works were then receiving the sewage of about 26,000 people and was hemmed in with shrubbery on a piece of ground which seemed to be not over an acre in area. No attempt is made there to treat the sewage further than by the tanks, the effluent from which is conducted to an open concrete lined channel leading down, eventually, to the Rhine.

The sludge accumulations at this plant, after five years of operation, were insignificant in volume, as farmers in the vicinity come and take it away, paying a small price per load for it. I doubt if its manurial value is high, but its spongy, light nature makes
36 it useful for plowing into heavy soils to render them more porous and more easy of cultivation.

Sprinkling Filters.

From the Imhoff tank the sewage will be conducted to a series of automatic flush tanks, which will discharge the sewage intermittently in a spray over the surface of the filters.

The filters will be built in beds with concrete floors draining to a general collecting channel leading to the secondary settling tanks. The filters will be built up of coarse gravel, or stones, from about 1½ to 2½ inches in size, and thoroughly underdrained with special tiles to permit the free passage of air entirely through the beds from top to bottom.

Such filters, when the rate of operation is properly adjusted to the character of the sewage, the depth of the filtering materials and the areas of the beds, will change the organic matters in the sewage to a condition not subject to subsequent putrefaction. When the sewage sprayed upon the filters is fresh no offensive or objectionable odors result, but when septic or rotten sewage is sprayed into the air the sulphuretted hydrogen and other gases escape, and may be carried by the winds for some distance, and create very offensive conditions, particularly in the immediate neighborhood of the plant.

The processes which go on in sprinkling filters, when properly designed and operated, produce no odors, as no slow decomposition goes on in the beds. The action is rapid and is brought about in the thin films of sewage flowing slowly over the surfaces of the stones in complete contact with the air, and the effluent from the filters, while more or less muddy in appearance, has no smell and will stand for a long time as inoffensive as ordinary gutter water in the streets after a rain. A small plant which I built last
37 year from the Pennsylvania Chautauqua Grounds, at Mt. Gretna, along lines somewhat similar to those proposed herein for Orange, Montclair and East Orange was shut down for the season during the early part of September, but the settling basins which had received the effluent from the sprinkling filters all summer were left standing full. I visited the works after this water had been standing for two weeks exposed to the sun and air, and it was then clear, without odor and like ordinary pond water, support-

ing on the surface a growth of green algae, and showing no signs of gray sewage fungi either in these basins or the channels leading from the sprinkling filters, and no odors were detectable about the filters. Stones dug up from some distance below the top of the filter had an odor such as if it had been just dug up from the ground; all traces of odors of putrefaction were absent. I am informed by people who repeatedly saw the plant in operation during the hot summer weather that there was no odor about the place except where a leaky valve from one compartment of the sludge chamber allowed a continual escape of a small amount of decomposing sludge. This was so small that the odor could not be noticed except in the immediate vicinity of the sludge bed upon which it flowed.

The Pennsylvania State Board of Health requires daily reports of the operation of this plant, and these show that no sample collected during the time the plant was in operation showed putrescibility when kept in stoppered bottles for 5 days, the stipulated time for the test. The superintendent kept several samples for much longer times, for his own information, one for two weeks, and it was still stable when he was obliged to throw it away for lack of bottles.

Secondary Settling Basins.

38 After passing through the sprinkling filters the sewage will go to the secondary settling basins or Imhoff tanks for the deposition of the suspended matters draining from the filters. The tanks would be built with much smaller sludge compartments, than the primary tanks and the deposits taking place therein would be pumped back, as required, to the primary Imhoff tanks, by a small pumping plant.

Machinery and Chemical House.

At a convenient location, probably near the primary and secondary Imhoff tanks, there will be a house containing the pumps for pumping the deposits which gather in the secondary Imhoff tanks to the inlet channel leading to the primary Imhoff tanks. The accumulations in these secondary tanks will be pumped out, as required, and after complete digestion in the primary Imhoff tanks be discharged upon the sludge beds. The service required of the pumps will be intermittent, and their period of operation short, so that elaborate machinery will not be required. The pumps could be driven by electric current, if this could be conveniently secured, or by gasoline engines.

In this house would also be located tanks for making up the necessary chemical solutions and devices for regulating the amounts to be used in accordance with the necessities of the case. Pipes from the house would lead to the various points where the chemicals would be introduced into the sewage.

Water Supply.

A supply of clean water will be essential at the plant for keeping the place clean and for making up the chemical solution. Water

may be had at this point by a connection with street mains about one-half a mile away, or, if preferred, an independent supply can be put in, taking water from the ground by means of a deep well, or a filtered supply sufficient for the needs of the plant could
39 be taken from the river. There would not be a great deal of difference in the cost of these methods, of getting a water supply.

Superintendent's Residence.

It will be advisable to have a well appointed house for the residence of the superintendent of the plant, who should be a man of experience and ability. It is possible that one of the houses now located on the site proposed for the works could be utilized for this purpose after remodeling. I have, however, included in the estimates of cost a sum sufficient to erect a new residence with proper water supply and plumbing.

General Maintenance of the Works.

After the works are completed it will be essential that not only the disposal plant, but also the trunk sewer and all the sewers in the towns of Orange, Montclair and East Orange be kept clean and in good repair in order that the sewage may be fresh when it arrives at the disposal works. To accomplish this end I would strongly recommend that the three cities appoint a commission to have charge of the construction of the disposal works and connecting sewers, and, after the works are built, to have charge of the operation of the process of purification and also of the maintenance and cleaning of the sewers in each of the three towns, as well as the main outfall sewer leading to the works.

The reason for this recommendation is that even though the disposal plant may be all that could be desired in the matter of design and construction, the superintendent of the disposal works might be greatly embarrassed if, through the neglect of any of the towns to keep the local sewers in repair, and properly clean, foul smelling sewage might arrive at the plant and give rise to disagreeable odors in the vicinity of the plant. If the entire sewerage works of the three towns are under the direction of a joint committee who
40 holds the superintendent of the disposal works responsible for their inodorous operation there would certainly be no odors detectable at the plant after it has once been put in proper and successful operation.

Estimates of Cost of Construction and Operation.

Based upon the data regarding the quantity of sewage to be treated and the general type of plant above described, I estimate the cost of construction to be as given in Table V.

TABLE V.

Estimated Cost of Constructing Sewage Disposal Works for Orange, Montclair, and East Orange (Including 15% for Engineering and Contingencies).

Population to be Provided for in First Installation, 133,000 (Estimated to be Reached by 1925).

Items.	Proportion of total cost of construction to be charged to each city on the basis of maximum rate of sewage flow in 1940.			Total Cost.
	Orange. (31.6%)	Montclair. (32.0%)	East Orange. (36.4%)	
Land for disposal works....	$39,500	$40,000	$45,500	$125,000
Joint sewers:				
From plant to junction of East Orange sewer.....	36,340	36,800	41,860	115,000
From East Orange sewer to junction of Orange and Montclair sewers	19,276	19,520	22,204	61,000
Purification works, including grit chambers, Imhoff tanks, sprinkling filters, secondary tanks, machinery and chemical house, water supply, sludge beds, piping connections, superintendent's house, grading, planting, etc.....	259,120	262,400	298,480	820,000
Totals	$354,236	$358,720	$408,044	$1,121,000

When the capacity of these works shall have been reached, 41 additional filters, tanks and sludge beds will be necessary. As these will not be required, however, for many years, the money necessary for their construction would not have to expended at the present time and the cost of such extensions, therefore, when required would be represented by the present worth of the money. The probable cost of these extensions would be about $188,000, but deferring the construction for 14 years (1911 to 1925) would give a present worth, interest at 4%, of $109,000.00, which, with 15% added, would be about $125,000.

The final cost of construction, therefore, for a population of 181,000, which is estimated to be reached by 1940, with the relative costs distributed to the three towns in the same ratio, as above, would be as given in Table VI.

TABLE VI.

Items.	Orange. 31.6%	Montclair. 32.%	E. Orange. 36.4%	Total.
Cost of first installation of works, as above.....	$354,236	$358,720	$408,044	$1,121,000
Present worth of new extensions in 1925, to serve until 1940	39,500	40,000	45,500	125,000
Totals	$393,736	$398,720	$453,544	$1,246,000

The annual cost of operating and maintaining the works would be made up of the interest on the cost of building the works, an allowance to provide for a sinking fund to retire the bonds, an allowance to cover the depreciation of the works, the salaries paid for labor, and the cost of fuel, chemicals and general supplies.

In the following estimates I have calculated the interest at 4½ per cent. and the sinking fund at 2 per cent. of the cost; the depreciation amounts are based on annuities sufficient to replace the perishable parts of the works at the end of their assumed usefulness; the items for labor include a superintendent and ten men,
42 who are to have charge of the works and the maintenance of the sewers in proper sanitary condition. The items of fuel, chemicals and supplies are based on the quantities of each which I estimate will be necessary. On the above basis the annual cost of operation would be as given in Table VII.

TABLE VII.

Annual Cost of Operation and Maintenance for a Population of 133,000.

(Estimated to be Reached by 1925.)

Items.	Orange.	Montclair.	East Orange.	Total.
Interest at 4½%	$15,941	$16,142	$18,362	$50,445
Sinking fund at 2%	7,085	7,174	8,161	22,420
Depreciation	790	800	910	2,500
Labor	3,100	3,200	3,640	10,000
Fuel, chemicals, etc.	3,100	3,200	3,640	10,000
Totals	$30,136	$30,516	$34,713	$95,365

For a Population of 181,000.

(Estimated to be Reached by 1940.)

Items.	Orange.	Montclair.	East Orange.	Total.
Interest and sinking fund	$25,593	$25,917	$29,480	$80,990
Other items	8,535	8,643	9,832	27,010
Totals	$34,128	$34,560	$39,312	$108,000

For the purpose of showing the relative costs of constructing and operating the plant recommended with the costs to the three cities under the plan proposed by the Passaic Valley Sewerage Commission in their report of 1908, I have arranged, from the data given in that report, the costs of construction, as given; and the annual costs of operation, with interest and sinking fund at 6½ per cent. and the other operating costs in the proportion of the use these towns would make of the sewer (as stated in the report) to the total capacity of the sewer, or, in the ratio of 37 to 360. This gives a cost
43 of $124,567 for interest and sinking fund and $29,000 for the other items, or a total, by 1940, of $153,567.

On these bases, the costs of construction of works sufficient for the population to be expected by 1940 would be as follows:

Estimated Construction Costs to Orange, Montclair, and East Orange of Joining in the Passaic Valley Sewer Project.

Cities.	Orange.	Montclair.	East Orange.	Total.
Costs	$418,800	$600,649	$898,871	$1,916,410

Estimated Annual Costs to Orange, Montclair, and East Orange of Joining in the Passaic Valley Sewer Project.

Cities.	Orange.	Montclair.	East Orange.	Total.
Fixed Charges	$39,363	$39,861	$45,343	$124,567
Other Items	9,164	9,280	10,556	29,000
Totals	$48,527	$49,141	$55,899	$153,567

A comparison of these figures with those for the plan recommended herein shows that it will cost the three cities nearly $670,000 more to join in the Passaic Valley Sewer project than to build a local disposal plant, and nearly $50,000 per year more to meet the necessary operating expenses of the Passaic Valley Sewer than of the plant recommended.

General Summary.

The plant recommended in the foregoing description, with extensions about 1925, will provide for the purification of the sewage of Orange, Montclair and East Orange until the population of these towns shall have reached about 181,000 people, which, I estimate, will be by 1940. All parts of the first installment of the works would be built to take care of a population of about 133,000
44 people except the sewers leading to the plant, which should have capacity sufficient for the population that will be reached by 1940. In the estimates of cost the sewer from East Orange is not included for lack of data as to its course. I have satisfied myself, however, that a sufficient head would be available, from the East Orange town line to the junction with the trunk sewer, to permit of the conducting of the East Orange sewage to the plant in a sewer having a self-cleansing grade.

If maintained with average care, and with an understanding of the nature of the processes to be carried out, and the proper methods of caring for the different portions of the works, the plant should prove a success in every way, and be devoid of objectionable features. The works will be situated in the low ground lying back from the Yantecaw River, and would be surrounded by hills rising up rather steeply from the valley to a height from 50 to 100 feet above the plant. On all sides except at one small corner, the tract of ground is covered with large trees that will hide it from view from the roads traversing around the district. The nearest houses to the plant at

present, except those situated on the tract where the works will be built, are about 1,000 feet away, and there are but two or three of these, and they lie in a position where the prevailing winds will blow towards the plant. By purchasing the tract of land outlined and preserving the trees thereon, and improving the landscape features of the situation by planting trees, shrubbery and flowers, the works could be made very attractive, and would become a centre of much interest for visitors.

There would be no odors connected with the spraying of the fresh sewage upon the sprinkling filters, and none connected with the handling of the sludge from the Imhoff tank, judged by the experience that has been had at other places dealing with stronger sewages of the same general character.

45 The effluent from the plant would go into the Yantecaw River, at all times, in better condition than the waters of the river, and would contain nothing that would injuriously affect any uses to which the water would properly be put for manufacturing or trades uses, or for its enjoyment in any proper way. The discharge of this effluent into the river would not cause the water to become foul, even though several times as great in volume as the river water during dry weather; it would, in fact, be a decided advantage to the river, and to the parties along the stream below, to have the additional flow during dry weather. On the other hand, during flood flows the increase due to the discharge of the effluent in the river would not perceptibly increase flood heights.

As to the absence of nuisance around installations of properly designed Imhoff tanks the best evidence is to be found in and around the City of Essen, Germany, where numerous such plants are situated in densely populated districts. By reference to Figure 1, which is a photograph of the Essen-North plant, it will be seen that directly back of the works is a row of large buildings, several stories in height. These stand about 500 feet from the tanks treating the sewage from 180,000 people, and are high class apartment houses. Figure 3 shows the plant at Recklinghausen, which receives the sewage from 26,000 people. This little plant stands on an area considerably less than an acre in extent, the area of the tanks being 0.05 acre and of the sludge drying beds 0.10 acre. The house close beside the plant is the residence of the superintendent of the works. On the opposite side of the works from the superintendent's house and, as I recollect the location, not more than 500 or 600 feet away, is a very fine detached residence; others are located around the same general neighborhood at various distances from the works, as can be seen in Figure 4. No complaint has ever

46 been made of odors at this plant, nor could I learn of anyone living in the vicinity who had found anything to object to about the works.

Figure 2 shows the sludge beds of the plant at Bochum, which receives the sewage from 150,000 people. High class residences surround the works, those shown being 400 to 500 feet away from the sludge beds.

At the time of my visit, when fresh sludge was drawn from the

tanks at my request, when freshly drawn sludge had been drying upon the sludge beds close beside the tanks for two days and when piles of dried and partially dried sludge were scattered about, a few hundred feet below the works, I could detect no odors about the place arising from the works or their operation. A view of the sludge beds at the Recklinghausen plant is given in Figure 4, and of those at Buchum in Figure 2. The houses shown near the sludge beds at Bochum are about 400 to 500 feet away.

Regarding the sprinkling filters, there is less definite information as to their inodorousness than about the Imhoff tanks. Unfortunately, all the large installations of sprinkling filters which I have visited are receiving septic or rotten sewage, and at most of these, though not all, there was more or less odor detectible at distances of from 200 feet to one-half mile, or more, depending upon the humidity, temperature, direction of the wind, and rottenness of the sewage. There are one or two plants in Europe of moderate size, which are handling fresh sewage, and in these the experience has been similar to the Mt. Gretna plant, in that the fresh sewage has not caused any odors at the sprinkling filters. Another curious circumstance is that at all these plants handling fresh sewage it has been noted that the small flies which are so abundant around most sprinkling filter plants have not, so far, appeared.

It is not necessary, in this report, to enter into a discussion
47 of the chemical and biological aspects of the treatment proposed herein, as I believe that you are more interested in securing my profesional judgment as to the general satisfactory condition of such a plant.

It is my judgment that there will be no difficulty in building and operating the plant recommended, in such a manner that it will not produce disagreeable odors at the plant, or in its vicinity, or along the Yanteeaw Valley; or cause the Yanteeaw River to be less desirable, at any time for any use to which it can now be put; or in any measurable degree increase the heights of floods in the river.

Respectfully,

JAMES H. FUERTES.

1 COMPLAINANTS' EXHIBIT No. 145. James D. Maher, Commissioner.

NEW YORK CITY, May 19th, 1913.

This certifies that a copy of the within report has been filed in the Mayor's office by the Metropolitan Sewerage Commission.

JAMES MATTHEWS,
Executive Secretary.

Report on the Discharge of Sewage from the Proposed Passaic Valley Sewer of New Jersey.

Metropolitan Sewerage Commission of New York.

May 23, 1910.

Honorable William J. Gaynor, Mayor of the City of New York:

SIR: In a report submitted by this Commission to your Honor on March 1, 1910, reference was made to a number of proposed trunk sewers which will add materially to the pollution of the harbor by carrying the sewage of inland cities to the immediate vicinity of New York City for disposal. One of these sewers is that of the Passaic Valley Sewerage Commissioners, of New Jersey. To prevent the execution of the Passaic Valley project a suit is pending in the United States Supreme Court between the People of the State of New York, complainants, and the State of New Jersey and Passaic Valley Sewerage Commission as defendants.

The United States Government by permission of the Court became a co-plaintiff in this suit, but has recently entered into an agreement with the defendants whereby the objections of the Government have been removed. It is expected that this agreement will be followed by the withdrawal of the State of New York, thus permitting the construction of the Passaic Valley sewer and the discharge of its sewage after partial purification, into Upper New York Bay.

The Metropolitan Sewerage Commission has given close attention to the Passaic Valley project since 1906. The question was also studied by the New York Bay Pollution Commission from 1903 to 1906. The Pollution Commission objected to it in general and specific terms, and recommended that the State of New
2 York bring action which is now pending in the Supreme Court of the United States to prevent the execution of the proposed works.

The plans for the works have been altered somewhat since this suit was begun, but they have not been wholly relieved of their objectionable features. The Metropolitan Sewerage Commission respectfully advises your Honor that the project as now announced should be opposed by the City and State of New York as involving serious danger of nuisance and injury to the public health.

Upon its face the present plan of the Passaic Valley Commis-

sioners appears to be a decided improvement upon the project formerly announced, but it is the opinion of the Metropolitan Sewerage Commission that the method of disposal is still objectionable. The degree of purification is insufficient. There are features connected with the outlets which are untried, experimental and of uncertain practicability. The agreement provides for the enforcement of the contract by the United States War Department instead of by the City or State of New York or an Interstate Commission, where jurisdiction over the sanitary condition of the harbor properly belongs.

Plan of the Passaic Valley Commissioners.

The proposition of the Passaic Valley Sewerage Commissioners is to collect the house drainage of Newark, Paterson, and about 30 other municipalities or townships in the Passaic Valley and discharge it into Upper New York Bay. This would be done by an extensive system of sewers and a tunnel running under Newark Bay, Bayonne and New York Bay to the neighborhood of Robbin's Reef. The tunnel would discharge the sewage through a number of outlets at the bottom of the harbor near the edge of the main ship channel. The sewage would be screened and passed through settling basins in order to remove solid particles of grit. The number of persons tributary to the sewer would be about 600,000 when the works were first put into operation. The quantity of sewage would increase with the population up to the full capacity of the sewer, when there would be about 1,650,000 people contributing their sewage to the works.

Insufficient Purification.

The purification intended would not be sufficient to admit of the discharge of the Passaic Valley sewage at Robbin's Reef. The process contemplated is designed solely to remove solid matters, and has no reference to the dissolved organic matters which may be present and from which a large part of the total nuisance may be anticipated. There will be little solid matter to be removed from the sewage. Owing to mechanical and biological actions in the sewer much of the solid matter will be broken up into extremely fine particles which will escape the screens and settling basins and pass into the harbor water.

Even the removal of a very large percentage of the suspended matter in the sewage would not purify the sewage to a satisfactory extent. Most of the organic matter in all sewage is present in dissolved form. Because of its long passage through the sewers the sewage will, in all probability, be in a septic, or rotten, condition and consequently very offensive.

Owing to its septic condition the sewage will have a great avidity for the oxygen dissolved in the harbor water, and the investigations of this Commission indicate that the supply of oxygen in the harbor is already deficient because of the sewage which is being discharged.

The discharge of so large a quantity of sewage into the harbor in one locality, even though the outlets be scattered over an area of several acres, would almost certainly result in the reduction of the dissolved oxygen at times of imperfect dispersion, and during times when the currents would be stationary or recently reversed, to so low a point as to invite putrefaction and the consequent evolution of foul odors from the water and sewage mixture. In this connection it should be remembered that the point of outfall would be in the land-locked part of the harbor, within sight of the most densely crowded business section of New York City within a distance of one mile of the Borough of Richmond and three miles of the Borough of Brooklyn.

Unusual Rights Apparently Granted by the United States Government.

The agreement entered into by the United States Government and the Passaic Valley Sewerage Commissioners contains the provision that the discharge of the sewage into the harbor at the locality chosen shall not reduce the available supply of dissolved oxygen in the water below the limit that would injuriously affect major fish life in the waters thereabouts. This provision apparently grants to the Passaic Valley Sewerage Commission the right to absorb all the margin of sewage capacity now remaining in the harbor waters, and opens the way to complications of a serious nature. The United States Government should not, and perhaps cannot legally grant to the Passaic Valley Sewerage Commissioners
4 the total or any definite proportion of the remaining capacity of the harbor waters to receive sewage.

Experimental Method of Discharge.

The method proposed for the discharge of the sewage beneath the surface of the harbor involves many constructional difficulties and uncertainties. It is not known that outlets of the form and character proposed can be constructed and maintained at the place designated. If, after the work on the tunnel shall have been partly or wholly completed, it be found that the system of outlets proposed cannot be built for the amount of money available, it is within the range of possibility that the plans now agreed upon would be changed to a simpler and less expensive form of construction to the material disadvantage of the method of disposal.

Extensive studies, including thousands of analyses, made by the Metroplitan Sewerage Commission concerning the quality of the water in Upper New York Bay, indicate that the discharge of sewage in the manner and in the quantities proposed by the Passaic Valley Commission would be attended by a heavy draft upon the capacity of the harbor for assimilating sewage. The quality of the water at the present time shows unmistakably the effects of the sewage now discharged into the harbor. The welfare of the cities situated upon the shores of the harbor requires that the water shall not be unnecessarily contaminated with the sewage of inland com-

munities. The burden of pollution should be increased only when strictly necessary, as where cities are situated on the water front and can provide no other method of disposal.

It is reasonably certain that a nuisance would appear at the outfall. The sewage from the Passaic Valley district cannot reasonably be expected to disappear without the production of local nuisance, including discoloration of the water, the appearance of greasy scum and offensive odors.

Availability of Other Methods of Disposal.

It is not the duty of the Metropolitan Sewerage Commission of New York to solve the problems confronting the Passaic Valley Sewerage Commissioners and state in detail what solution of this question should be adopted, but the plan proposed by the Passaic Valley Commission is not the only one available for disposing of the sewage.

It would be better, in the judgment of the Metropolitan Sewerage Commission, for the sewage of the Passaic Valley district to be purified upon the Newark meadows and the effluent discharged into Newark Bay. There is a large movement of tidal water in Newark Bay, and the saving in cost which would be effected if it were not necessary to construct an outfall tunnel beneath Newark Bay, the Bayonne Peninsula and New York Bay, with the expensive system of outlets proposed, would go far toward paying the cost of purifying the sewage to an extent which would make the discharge of the effluent into Newark Bay a safe procedure.

The suggestion that the Passaic Valley sewage be purified on the Newark meadows and discharged into Newark Bay should not be interpreted as an expression of opinion by the Metropolitan Sewerage Commission favorable to the Passaic Valley enterprise in any of its aspects. The collection of the sewage of that large territory to a central point for disposal is not the only way in which the sewage problems of the Passaic Valley can be solved. It might be more desirable to collect and dispose of the sewage of the different municipalities concerned on some other basis, as, for example, by a number of sewerage districts and at a number of sewage disposal plants. Favorable reports upon such projects have been made by eminent engineers at the instance of the City of Paterson in the Passaic Valley district.

The Secretary of War as Referee.

The agreement entered into between the United States Government and the Passaic Valley Commission stipulates that the sewage would produce no effects objectionable to the Secretary of War of the United States, either through interference with the navigable character of the channels or through the production of nuisance or conditions injurious to the public health. The agreement mentioned does not give adequate assurance to the people of New York

City and State that the Passaic Valley project will not become a public nuisance, and the method of enforcing the agreement is open to criticism.

The agreement is between the Passaic Valley Sewerage Commissioners and the United States through the Secretary of War. The War Department is not a legal health authority and has no responsibility of a sanitary nature toward the State of New
6 York or New York City. If the Passaic Valley sewage became a serious nuisance or menace to health to the people of New York City or State, it could not properly be objected to by the Secretary unless injury were done to the property of the United States Government. This property, including, principally, fortifications, is of insignificant character as compared with the interests of the City and State of New York.

Were the Passaic Valley sewage to produce a nuisance or substantial injury to the health of the cities situated upon the harbor of New York, there would be no way to stop the nuisance except by long and tedious litigation and the construction of extensive public works. Once the Passaic Valley sewer was built and in operation it would be impracticable to put a stop to the discharge of sewage through it, for the cities tributary to it would then have no other outlet for their offensive and dangerous wastes.

Action Recommended.

The present status of the Passaic Valley case is as follows: The State of New York brought suit against the Passaic Valley Sewerage Commission and State of New Jersey in the United States Supreme Court to prevent the execution of the Passaic Valley project. The United States Government requested and obtained permission to intervene in this suit and become a co-plaintiff in order to protect United States property in New York harbor against injurious consequences from the sewage. An agreement was thereafter entered into between the United States and the defendants whereby the latter agreed to purify the sewage to an extent and in a manner specified, on condition that the United States would withdraw from participation in the suit. This agreement has been ratified by the New Jersey Legislature and by the United States Attorney General. The suit still continues as between the State of New York and the defendants, but it is expected to be withdrawn unless continued for some unexpected reason.

The Metropolitan Sewerage Commission of New York recommends to your Honor that The City of New York take steps to assert its legal rights in the premises, and it is suggested that application be made to the United States Supreme Court for permission to intervene in the suit in order to become a co-plaintiff, to the end that public health and welfare in The City of New York shall be adequately protected.

A large amount of technical information bearing upon
7 the capacity of New York harbor to assimilate and otherwise dispose of the sewage of the Passaic Valley, and data concern-

ing the probability of a nuisance from this source are contained in the report of the Metropolitan Sewerage Commission dated April 30, 1910.

Respectfully submitted,

METROPOLITAN SEWERAGE COMMISSION OF NEW YORK.

1 COMPLAINANT'S EXHIBIT No. 146. James D. Maher, Commissioner.

NEW YORK CITY, May 19, 1913.

This certifies that a copy of the within report has been filed in the Mayor's office by the Metropolitan Sewerage Commission.

JAMES MATTHEWS,
Executive Secretary.

Report on the Proposed Discharge of Sewage From the Bronx Valley Sewer.

Metropolitan Sewerage Commission of New York.

July 25, 1910.

Honorable William J. Gaynor, Mayor of The City of New York:

SIR: The object of this report is to recommend that The City of New York take action to prevent the discharge of crude sewage from the Bronx Valley sewer. The sewer is now in process of construction. It is intended to discharge its sewage into the Hudson River immediately outside of the New York City boundary. The plans are for works to accommodate the sewage of an ultimate population of 850,000 people.

The Metropolitan Sewerage Commission of New York brings the project of the Bronx Valley Sewer Commission officially to the attention of The City of New York and, after pointing out that the regular machinery of the State for the protection of public health has been made inoperative, recommends that The City of New York take such action through its legal department as may be necessary to safeguard the interests of its citizens in this matter. It is suggested that appropriate action lies in an application to the United States Supreme Court for permission to intervene in the suit of the United States vs. the State of New York and Bronx Valley Sewer Commission in the United States Supreme Court in order that The City of New York may become a co-plaintiff with the United States and have a voice in the proceedings.

Early Opposition to the Bronx Valley Sewer Project.

2 Permission for the construction and maintenance of the Bronx Valley sewer was given by special act of the New York Legislature approved May 26, 1905, and amended by subsequent acts.

Early opposition to the project was made by the Metropolitan Sewerage Commission of New York. In a letter dated September 18, 1906, the Metropolitan Sewerage Commission addressed a communication to the Chairman of the Bronx Valley Sewer Commission, pointing to the absence of provision in the Bronx Valley sewer plans for purifying the sewage before discharging it into the Hud-

son, showing the feasibility of purifying sewage, explaining the probable need of treating the Bronx Valley sewage, and recommending that provision be made in the plans for at least the minimum measure of treatment which future studies might show to be necessary. This communication led to conferences between the Bronx Valley Commission and the Metropolitan Commission, during which the subject was more fully discussed. The conferences were without result. The Metropolitan Commission had no authority to enforce its recommendations and it was impossible by other means to induce the Bronx Valley Sewer Commission to alter the plans.

At a hearing on the Bronx Valley project before the State Commissioner of Health and State Engineer and Surveyor in December, 1906, the Metropolitan Sewerage Commission registered official protest against the Bronx Valley sewer project on account of its failure to provide purification for the sewage before discharging it into the Hudson River. Under the general laws of New York State, all plans for sewerage and sewage disposal must receive the approval of the Health Commissioner and State Engineer and Surveyor before they can be carried out.

At the hearing just mentioned, protests were also made and petitions filed by organizations representing the entire trade and commerce of The City of New York. The civic bodies included the Chamber of Commerce of the State of New York, the New York Produce Exchange, the Maritime Association of the Port of New York, the Merchant's Association of New York, the New York Board of Trade and Transportation, the West End Association and the American Steamship Association.

These protests were without avail, for the State Engineer and the State Commission of Health had apparently been deprived of their usual functions with respect to this sewerage project. It was presently declared by the Attorney General of the State that the special act of Legislature under which the Bronx Valley Sewer Commission existed placed the operations of that commission outside the jurisdiction of the State Commissioner of Health and the State Engineer and Surveyor. The Legislature had apparently
3 given permission to the Bronx Valley Commission to discharge its sewage into the Hudson River without regard to consequences.

At the present time the State of New York is being compelled to defend the construction of the Bronx Valley sewer, having been placed in this position by the United States Government. A suit for a permanent injunction to prevent the construction and operation of the sewer is pending in the United States Supreme Court between the United States on the one side and the State of New York and the Bronx Valley Sewer Commission on the other. Pending trial of this suit, the work of constructing the sewer is being pushed rapidly. Because of the rapidity of construction and delays attending the suit, it is now proposed by the United States Department of Justice to apply to the United States Supreme Court for an injunction which will stop the work until the trial determines whether a permanent injunction shall be issued.

The suit brought by the United States against the State of New York and the Bronx Valley Sewer Commission is based on the injury which the Bronx Valley sewer is expected to do to property of the United States situated in New York Harbor, to the health of soldiers and sailors, and to the navigable channels which are the particular concern of the Government of the United States. The bill of complaint is a concise and conservative statement of the magnitude of the port, its importance as a commercial centre, the nature and cost of the harbor channels and other facts of interest in the case. A number of expert opinions with respect to the consequences to be apprehended are quoted from reports of United States Army officers of high rank and recognized sanitary experience. It is expected that arguments in the case will be heard in the autumn of 1910.

Necessity for Action by The City of New York.

Although likely to be seriously affected by the outcome of the case, The City of New York has, up to the present, taken no part in the legal proceedings against the Bronx Valley sewer project. The City has not been officially apprised of the situation or advised to take any legal steps in the matter. The time has now arrived when appropriate action should be taken. Information has come into the possession of the City to show the consequences which may reasonably be expected if the Bronx Valley sewage is discharged in the manner and quantity proposed. This information, collected by the Metropolitan Sewerage Commission is believed to be sufficient to make effective protest in a court of law.

4

The objections which are here made against the Bronx Valley sewer are similar to those already urged against the Passaic Valley sewer. The opinion of the Metropolitan Sewerage Commission concerning the Passaic Valley project has already been formulated and officially brought to the attention of the Mayor of The City of New York with the recommendation that the City become a co-plaintiff with the State of New York in a suit now pending in the Supreme Court at Washington, between the State of New York on the one side and the Passaic Valley Sewerage Commission and the State of New Jersey on the other, to prevent the discharge of sewage in accordance with the plans of the Passaic Valley Sewerage Commissioners.

The Bronx Valley and Passaic Valley projects belong to a class of drainage schemes to which the Metropolitan Sewerage Commission and its predecessor, the New York Bay Pollution Commission, have registered repeated protests. These protests have been made without respect to the governmental boundaries in which the sewers are built or within which they produce their worst effects. The chief ground for objection lies in the fact that such sewers are intended to carry to New York Harbor, already too heavily polluted with the sewage from the dense populations crowded upon its shores, large quantities of sewage from inland communities, which can provide other means of dealing with this waste.

Essential Facts Concerning the Bronx Valley Sewer.

The Bronx Valley project is of great magnitude. The total area in the assessment district is 35 square miles. The present population is about 30,000 and the ultimate population expected is 850,000. The daily discharge of sewage provided for at the commencement of operation is 3,000,000 gallons, and the ultimate discharge 90,600,000 gallons. The cost of the works, up to the time of opening, including expenses for land and incidentals, as estimated at $2,256,000. The sewer will begin at the northern boundary of White Plains and pass through Scarsdale, Tuckahoe, Bronxdale and part of Yonkers and Mount Vernon. The diameter of the sewer at its upper end is to be 3 feet 4 inches and at its lower end 8 feet 6 inches. The sewer is intended to carry only household drainage. Storm water is to be excluded. The total length of the sewer is to be 14 miles. The outlet is to be about 300 feet north of the point where the northerly line of the City of New York intersects the Hudson river.

The outlet, as planned, is to consist of two lines of 48-inch cast iron pipe, extending to a point in the river 500 feet from the shore and 40 feet below the surface of the water.

The theory upon which the sewage is to be emptied into the river is that the sewage will be mingled with and dispersed by the water of the river with such speed and completeness as to disappear. Disposal beneath the surface in the manner proposed is an improvement upon discharge at the surface, but the Metropolitan Sewerage Commission is of opinion that the sewage would not satisfactorily disappear under the conditions stated.

Probably the best example in the United States of a large quantity of sewage discharged beneath the surface of tidal water is afforded at Peddock's Island in Boston harbor. Here 40,000,000 gallons of sewage per day is discharged through a single outlet located 30 feet beneath the surface. Contrary to the theory of immediate disappearance, the sewage at Peddock's Island rises at once and make its appearance at the surface in a dense, discolored and offensive stream. The solid matters of the sewage rise with the liquid portion, particles of paper, fruit peelings and excrement being easily distinguishable. Traces of the sewage are sometimes visible for more than a mile.

Aside from the local nuisance which would be produced, the Bronx Valley sewage would add a considerable burden of impurities to the water which would have to be flushed away or assimilated by the water. As will be more fully explained, the flushing action of the harbor is incomplete and irregular. Most of the sewage which is discharged into it must be absorbed. The disappearance of the sewage depends upon the liquefaction and assimilation of the organic constituents. These processes are carried on largely through the activities of low forms of life natural to the water, such as bacteria and infusoriæ. When the quantity of sewage is so great as to overcharge the capacity of these agencies, disagreeable consequences

follow, notably discoloration of the water, evolution of foul odors and deposition of solid matter.

In New York harbor, deposits often occur near sewer outlets, and putrefactive changes, with the escape of offensive gases, take place. When the Bronx Valley sewer is first put in operation, the solid matter in the sewage will reach 1,400 tons per annum. This amount will be increased to at least 36,000 tons when the capacity of
6 the sewer is reached. In addition to this solid matter, large quantities of decomposing organic matter will be discharged in liquid form.

Present Sanitary Condition of New York Harbor.

The present condition of New York Harbor has been ascertained by studies, extending over several years, by the Metropolitan Sewerage Commission and the New York Bay Pollution Commission. Thousands of bacteriological and chemical analyses have been made of the waters at all depths, at all seasons and at practically all points. Studies of the tidal phenomena have been made and the intermixtures of ocean water and water brought down by the Hudson and other rivers have been determined daily for one year. Some of this work has been done in co-operation with the United States Coast and Geodetic Survey, experts of that branch of the government having, at the request of the Metropolitan Sewerage Commission, made an exhaustive research and compilation of all existing data in their possession relating to the direction of currents and the quantities of water flowing in and out of New York Harbor.

From these studies, the Metropolitan Sewerage Commission has deduced many facts with relation to the capacity of New York Harbor for sewage, the most important of which is that the harbor is far less capable of disposing of sewage in an inoffensive and sanitary manner than is commonly supposed.

Contrary to a belief now popularly held and formerly supported by apparently strong technical authority, the principal result of the movement of sea water in New York Harbor is to cause the sewage which is discharged into it to oscil-ate back and forth near the sewer outfalls. The harbor is not effectively flushed out by the tides. Aside from the water which is brought down by the Hudson and other rivers, there is practically no more water flowing seaward than landward. In certain parts of the harbor stagnation occurs. The condition of the waters in the open main channels makes it plain that sewage must be kept out of the harbor as far as it is practicable to keep it out.

The digestive capacity of the harbor for sewage has a limit. If this limit is passed, the water will become black, foul-smelling and putrid. Obnoxious gases will arise from it. In parts of New York Harbor such conditions as these now exist and are becoming more extensive as time passes. At present they are located for the most part in closely built-up factory sections, but their injurious
7 effects extend beyond local limits, and contribute to the polluted condition of the whole bay.

It has been found that practically the whole of upper New York Bay and the lower Hudson are underlaid by an accumulation of foul-smelling, black ooze in which fragments of sewage origin are readily discoverable. These deposits are of considerable thickness, sewage matters having been brought up from a depth of ten feet below the surface of the mud.

As might be expected under the circumstances, the number of bacteria in the harbor water is excessive. While clean sea water generally contains not more than a few hundred bacteria per cubic centimeter, the polluted waters of New York Harbor contain thousands. The average of a large number of analyses shows that the number of bacteria in the lower bay is about 1,300 per cubic centimeter of water; in the upper bay about 14,500; in the Hudson River, opposite Manhattan, about 6,600; in the vicinity of the proposed outlet of the Bronx Valley sewer the average number of bacteria per cubic centimeter has been found to be about 5,300. Intestinal bacteria are to be found everywhere. The water north of the Narrows is unsuitable for the cultivation of shellfish and dangerous to bathe in. The collection of driftwood for fuel is attended by considerable risk of disease.

The condition of the water with respect to its capacity for absorbing sewage without producing great offense is well indicated by the quantity of dissolved oxygen which the water contains. Sewage draws upon the oxygen supply, and when the oxygen in the water is exhausted the organic matter in the water putrefies. While clean sea water and uncontaminated river water normally contain 100 per cent of oxygen, the water of upper New York Bay contains but 67 per cent.; the Hudson River, opposite Manhattan, 72 per cent.; and the water near the proposed outlet of the Bronx Valley sewer, 83 per cent. of the quantity of oxygen which it should have.

The movement of the main tidal currents which oscillate backward and forward in New York Harbor has been well shown by floating objects which have been set adrift by the Metropolitan Sewerage Commission. There have been over seventy experiments of this kind. Some of those floats have been followed day and night by means of boats. One such float was started at the beginning of an outflowing tide on November 10, 1909, at 8.25 A. M., at Spuyten Duyvil, about three miles nearer the ocean than the proposed outlet of the Bronx Valley sewer. It flowed up and down in the Hudson, back and forth in the Upper Bay and to and fro in the Narrows until, on November 12, at 2.20 A. M., it had reached a point opposite Coney Island in the Lower Bay. Three times the direction had been reversed by the currents. For two days the float had drifted about the harbor. It had covered a total distance of 63¼ miles, while the direct distance from start to finish was 24½ miles. The conditions on this occasion were by no means unusual. The float was started at a stage of tide which was distinctly favorable to a prompt and direct passage to sea.

Summary of Objections to the Bronx Valley Sewer Project.

The objections which careful inquiry has shown to exist with respect to the Bronx Valley project are numerous and cannot all be stated here. Perusal of the foregoing pages will show their general nature. For convenience, a few of the main considerations which are opposed to the discharge of crude sewage from the Bronx Valley sewer follow:

1. The project would increase the pollution of the harbor as a whole and add materially to the pollution of that port of it where the sewer would discharge.

2. The proposed outlet is so near the New York City line that property in the city would be as surely affected as if the sewer was made to discharge within the city limits. Being outside of its boundaries, the City of New York would have no jurisdiction over the outlet.

3. Land in the neighborhood of the outlet is occupied by high-class residences and by large philanthropic institutions, chiefly homes for children. It is estimated that one thousand children reside in the neighborhood of the proposed outlet.

4. At the present time, sewage from the City of Yonkers, discharging about a mile above the proposed outlet of the Bronx Valley sewer, can sometimes be seen flowing down the Hudson in a stream for several miles. The sewage from the Bronx Valley sewer would increase this sewage stream and add to the consequent dangers and annoyances.

5. Objections to the Bronx Valley project exist in the fact that it is opposed to the policy of protecting the harbor which has been officially formulated by the State and City of New York through the Metropolitan Sewerage Commission.

6. In all the ways in which the pollution of the Hudson
9 River and New York Harbor may affect public health and comfort, the discharge of sewage from the Bronx Valley sewer would be an aggravating and growing factor.

7. Objection against the discharge of crude sewage from the Bronx Valley sewer exists for the reason that it would benefit one section of the metropolitan district at the expense of others. It should be a subject of mutual effort to keep the harbor clean as it is a matter of importance to all the people of the metropolitan district, in a part of which the Bronx Valley sewer is located. The City of New York, the chief offender against this policy as matters have stood in the past, is taking active steps to deal with its sewage in a sanitary manner.

8. The first step toward the protection of the harbor was taken by The City of New York when the Metropolitan Sewerage Commission was created to make an official study of the conditions of sewage disposal, and formulate a general plan or policy of conservancy for the metropolitan district of New York and New Jersey without respect to state or municipal lines. This investigation, made with strict impartiality, and involving the study of conditions outside as

well as inside of the limits of New York City, was paid for by The City of New York for the common good.

A second step taken by New York City for the protection of the harbor was made when the Legislature, at the request of the City, extended the life of the Metropolitan Sewerage Commission from May 1, 1910, to May 1, 1913, in order for it to make plans and estimates for the works necessary to protect the harbor as far as practicable from the sewage of New York City.

9. Objection to the Bronx Valley project exists for the reason that the evil consequences which will result will not be occasional or temporary, but continuous and increasing. The quantity of sewage will become greater as time proceeds, but the quantity of water into which it will be discharged will remain always the same. It is well within the range of probability that the estimates of future population of the Bronx Valley sewer district are too low, and that the remarkable growth of population now taking place in all parts of the suburbs of New York will make necessary a parallel sewer through the Bronx Valley, which will greatly increase the expected quantity of sewage discharged at the proposed outlet.

10. Objection to the Bronx Valley project arises from the fact that if no means for purifying the sewage are now provided, or land procured for the same, such works may prove impracticable to construct or locate in future without incurring greater expense than the residents of the Bronx Valley district are able to meet.

11. The Bronx Valley Commission cannot lay claim to unexpected insistence upon the purification of its sewage. They were notified by the Metropolitan Sewerage Commission in 1906 that they should make provision for such purification works as might eventually be found necessary.

12. Objection to the Bronx Valley project lies in the fact that special legislation took from the State Department of Health the jurisdiction which the general laws of the State intended that department to exercise over all questions of sewerage and sewage disposal. The State Department has, within recent years, made commendable efforts to protect the purity of the rivers of the State, yet the discharge of the Bronx Valley sewer, intended ultimately to dispose of a larger quantity of sewage than is produced by some of the cities of the State, is beyond the control of any sanitary authority.

Respectfully submitted.

JAMES MATTHEWS,
Executive Secretary.

Preliminary Reports on the Disposal of New York's Sewage.

I.

Study of the Collection of the Sewage of New York City to a Central Point for Disposal.*

Metropolitan Sewerage Commission of New York: George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sooysmith, Linsly R. Williams, Commissioners.

SEPTEMBER, 1911.

1 Study as to the Feasibility and Desirability of Collecting the Sewage of New York City at a Central Point for Disposal.

It has occasionally been suggested by engineers and others who have recognized the need of stopping the pollution of New York harbor that all the sewage be collected into one system of main drainage and pumped out to sea.

The benefits which would accrue from this solution of the sewage problem are so apparent that the Metropolitan Sewerage Commission of New York has given serious attention to the practicability of such a project. The following report is intended to describe the essential engineering features of the four forms of this general project which have seemed to the Sewerage Commission most promising. It would be within the range of engineering ability to carry out any of them, but the Commission considers that the benefits which would be secured would not be sufficient to justify their cost.

The point suitable for the outlet of a sea-going tunnel would depend upon the quantity of sewage to be discharged and the uses to which the neighboring shore might be put. The larger the quantity of sewage to be disposed of, the farther the outlet should be from land. Other considerations affecting tthe location are the condition of the sewage with respect to the solid matter contained, the presence or absence of putrefaction, the action of the tidal currents and the uniformity or intermittency of discharge.

* This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service. Some features of this report will remain open for revision until the final report is submitted.

The territory which might appropriately be included in a drainage system whose object was disposal of the sewage at sea could apparently include the metropolitan district of New Jersey as well as New York. No insuperable reason is apparent why the two states should not unite in the construction of a single system of main drainage. The quantity of sewage to be disposed of would therefore be the quantity which would be produced in New York and New Jersey within about twenty miles of the New York City Hall.

Either Long Island Sound or the Atlantic Ocean might seem to afford a suitable site for the discharge of the sewage. There is, however, no point in Long Island Sound, within reasonable distance, where the waters are sufficiently open and where the outlet could be sufficiently far from inhabited shores to make the discharge of such a large quantity of sewage free from objectionable consequences. The extensive use of the bottom of Long Island Sound for the cultivation of oysters also makes these waters unsuitable. The Atlantic Ocean would be the only place which would be suitable for the discharge of the sewage. The condition of the sewage would neither
2 favor nor hinder its prompt disappearance. The largest solid materials would be removed by screens for the protection of the pumps which would be required to force the sewage to the outlet, and some solid matter would be broken up by the passage of the sewage through the sewers, so that the matters left in suspension would be in finely divided condition.

The length of the sewers would be so great that the sewage would be in a state of decomposition by the time it reached the outlet and would therefore be more offensive than fresh sewage. In consequence of this fact, the water in the vicinity of the outlet would be more offensively polluted than it would be were the sewage to be discharged in fresh condition. The distance of the outlet from the shore should be correspondingly greater.

Just how far the outlet should be from shore is not susceptible of exact determination. From six to ten miles seems not too great a distance in view of the re-entrant angle formed by the coast line and the large number of residences and summer resorts along the beaches.

Continuous Discharge at Sea.

Experience shows that the sewage would mingle slowly with the sea water. It would, in all probability, rise in a column from the outlet at the bottom and flow away at the top, its destination as sewage being determined partly by the tidal currents, partly by the force and direction of the wind and partly by the intermixing action of the waves.

Studies have been made by the Sewerage Commission of the tidal currents and effects of wind at sea near the location which might be selected for the outlet. Opportunity to investigate this subject was afforded in the year 1906, when the garbage of New York City was being dumped at sea during a temporary suspension of the reduction plant at Barren Island, where the garbage is customarily dealt with. The point selected for sea-dumping of garbage was seventeen miles

southeast of the fairway buoy at the entrance of Gedney Channel. This point was about fifteen miles from the New Jersey and New York shores. Inspectors employed by the Sewerage Commission examined the beaches over a period of some weeks and investigators for the Commission cruised about upon the waters to note the presence and distribution of the refuse.

It was found that the garbage remained in floes or fields for long periods of time. It traveled at rates approximating a maximum of two miles an hour under what appeared to be normal conditions of wind and tide. There was a distinct fouling of the shore lines over a distance of fifty miles from New York along Long Island and seventy-five miles along the New Jersey coast. Some 3 of the floating material returned to New York and was found moving into the inner harbor through the Narrows.*

Wind undoubtedly had an effect upon this floating refuse, but wind would also have an effect upon the movement of sewage. Wind moves the whole surface of the water upon which it blows, as has frequently been observed by the Commission in studying the behavior of sewage in Upper New York Bay.

An examination of the depths of water along the New York and New Jersey coast lines, as recorded upon the official charts of the United States Coast and Geodetic Survey,† shows that there is no point available at a distance of ten miles from shore where a sea-going tunnel could well be built. As the bottom for the most part is sandy, a tunnel would have to be built by compressed air. The depths required would exceed 120 feet, which is about the limit at which it is practicable to use the process. There would be serious difficulties, although not insuperable ones, in the construction of any long tunnel to sea.

From considerations of cost, excessive depth and magnitude of construction, the plan of carrying all the sewage of New York and New Jersey to sea is considered by the Sewerage Commission to be impracticable.

If New Jersey were left out of the project and New York undertook to discharge its own sewage at sea, the engineering problems would be somewhat simplified, but they would not be reduced to the range of practicability. The quantity of sewage would be approximately four-fifths of that of the entire territory. The tunnels could be fewer in number and the distance of the outlets from the shore less, but the general nature of the works and the difficulties of construction would be similar. The construction of the sea-going tunnel and its outlet would still be a great obstacle.

Discharge at Sea on Outgoing Tidal Currents.

The length of the sea-going tunnel could be materially shortened if the sewage could be stored temporarily on shore and discharged only on outgoing tidal currents. In this case the full benefit of the

* Report Metropolitan Sewerage Commission of New York, April 30, 1910, pp. 380-388.

† Chart No. 120, United States Coast and Geodetic Survey.

transporting power of the water as it moved from the land could be utilized to carry the sewage as far away as possible.

This modification or any other departure from the plan of a continuous sea-going sewage discharge has seemed to make it necessary to exclude New Jersey sewage from consideration. It has
4 seemed unwise to the Sewerage Commission to suppose that the people of New York would consent to receive New Jersey sewage for disposal on New York soil, or vice versa.

Considering that New York's sewage was alone to be disposed of and that the discharge at sea was to take place only on outgoing currents, it is considered by the Sewerage Commission that the outlet could be located within about five miles from shore. A point suitable for departure from shore would be in the vicinity of Rockaway Point, with storage basins situated in the neighborhood of Barren Island. Because of the necessity for discharging intermittently, the tunnel capacity would have to be larger than would be required for continuous discharge.

It has been estimated that the quantity of sewage to be disposed of in 1940 would be 1,330,000,000 gallons per day. (See Appendix A.) This would be discharged in two periods of four hours each. The storage basins and pumping station would have to cover an area of 125 acres and have a depth of 20 feet to store the sewage during the periods when suitable seaward-moving currents were not flowing. There could be 4 tunnels of 18 feet diameter each. The tunnels could ran parallel to one another until near their outer ends, when they would separate to some extent. (See Appendix B.)

To collect the sewage to the vicinty of Rockaway Point for disposal at sea, there would be need of a system of collecting and intercepting sewers running to all parts of New York City. Staten Island would be connected by a tunnel beneath the Upper Bay. Manhattan would be provided with intercepting sewers running around the water front. The sewage would pass under the East River to large collecting sewers which would thence flow in the direction of the storage reservoirs near Barren Island. The sewage of Brooklyn would be collected by interceptors and collectors. A branch would run to The Bronx and another to a central point to take in the sewage of Northern Queens from the vicinity of Flushing. The sewers of this main drainage system would be of large magnitude, some of them approaching the dimensions of rapid transit subways.

To a large extent the present sewerage systems which receive the sewage directly from the houses would be utilized. The object of the main drainage works would be to collect the sewage from these sewerage systems and carry it to the disposal works.

As far as estimates have been made, it appears that the plan of collecting the sewage of New York to a central point and discharging it at sea on outgoing currents should not be recommended because of its cost. It is believed that the works would cost not less than $140,600,000. (See Appendix B.) It is possible that
5 such works may be needed in the remote future, but for the

present their large cost does not seem to be justified by the benefits which they would confer.

Application of the Sewage to Farm Land.

If the sewage of New York was collected to a central point for disposal, it could be dealt with in other ways than by discharge at sea. The sewage could be utilized by employing it for agricultural purposes or it could be purified to such a degree that the effluent would be non-putrescible and harmless. The Commission does not consider that either of these two latter plans is necessary or desirable, but it may be well to refer to some facts which should be taken into consideration in discussing the feasibility of these two procedures. Many persons have favored disposal on land, assuming that the sewage could in this way be turned to profitable use instead of being wasted. Intensive purification also has its advocates. The remarkable progress which has been made in employing bacteria and other agencies to carry on the purification of water and sewage under conditions which could be controlled lends considerable interest to this subject.

Considering first the possibility of applying the sewage to farm land, it is necessary to determine where the sewage of New York could be carried for disposal and how much land would be needed.

If the sewage of New York was to be disposed of on soil within the State, it would have to be taken to Long Island, for there is no other land within reach which has a suitable elevation and is of suitable quality. Long Island is low, flat, sandy and accessible.

To carry the sewage to Long Island for disposal on land, it should be collected first to a central point and from there pumped to the irrigation fields. A suitable central point would be in the vicinity of Jamaica. A system of main drainage including collectors and interceptors to carry the sewage which had been gathered by the lateral sewerage systems of the Metropolis would lead to a main pumping station. From the pumping station conduits would be needed to carry the sewage to the disposal fields. It would probably be economical to construct three such conduits with a diameter of 19 feet each. The fields might begin in the vicinity of Amityville, a distance of about thirty miles from the New York City Hall. Any point nearer would be unsuitable for the disposal of a large quantity of sewage because of the numerous villages, towns and other suburban settlements which exist.

About 175 square miles of land would be needed on the assumption that 12,000 gallons of sewage could be utilized per acre
6 per 24 hours. This is the highest rate which should be allowed. A tract of suitable elevation and of proper quality of soil can be found running from Amityville to Quogue, a distance of about fifty miles.

From an engineering standpoint, the idea of applying sewage to the sandy soil of Long Island is feasible. It is estimated that the cost of the works necessary would be about $153,000,000. (See

Appendix C.) The purchase of the land would add greatly to the above cost.

There are apparently insuperable obstacles to the successful carrying out of this project. Aside from the great cost of works and of land, it would be necessary to eliminate villages and towns and to acquire the right to the property of many large estates and public institutions or provide a larger total area than that mentioned. More important still, a part of the water supply of New York might be seriously interfered with. A large part of the drinking water for Brooklyn is obtained from wells on the south side of Long Island, and it seems improbable, even if no injurious consequences followed to the water, that public opinion would permit the sewage of the Metropolis to be disposed of on the same land from beneath which the water was derived.

Passing now from a consideration of the feasibility of disposing of the sewage upon farm land to the possibility of dealing with it by intensive purification, we may take up the last problem of handling the sewage after collecting it to one central point.

Intensive Purification of the Sewage.

For disposal by intensive purification, the sewage would be brought to a central point by a system of main drainage, including such collectors and interceptors as have already been sufficiently described.

The place to which the sewage would be brought could conveniently be the vicinty of Jamaica Bay.

The process of purification would presumably be settlement for the removal of the larger solid impurities and biological treatment for the oxidation of the dissolved organic matters. If the effluent, after purification, was to be discharged into the waters of Jamaica Bay or near the shore of the ocean, it could be disinfected so that it would practically, if not completely, be free from disease germs.

It seems unnecessary to describe the details of the purification which should be employed. It is well within the range of engineering ability to construct the works and to produce an effluent of any required degree of purity. Estimates have been made of the cost of intensive treatment, assuming that disinfection would not
7 be necessary, but that settlement followed by oxidation in sprinkling filters would be the most desirable process. The collection and treatment works would cost approximately $141,000,000. (See Appendix D.)

This sum, in the opinion of the Sewerage Commission, is a very large price to pay for the results which would be accomplished. It is, in the Commission's view, unnecessary at the present time to construct such a complete system of main drainage as would be required in order to collect all the sewage of the Metropolis to one central point.

Desirability of Subdividing the Territory for Sewage Disposal.

The plan of collecting all the sewage to a central point for disposal is, fortunately, not the only way to protect the harbor against

sewage pollution. It is the opinion of this Commission that works of less magnitude and cost can be constructed to answer all the requirements of the harbor, as a whole, and with special regard to the needs of certain localities.

Fundamental to the design of such large sewers, treatment works and outlets as are required, is a division of the metropolitan territory of New York into districts. The boundaries of these districts should coincide approximately with the principal natural drainage areas of the land. The sewage should be collected and treated in each of these districts in such ways as to afford all the relief needed for the near future, and their design should be such as to fit into a more comprehensive plan, if more protection is needed at a distant time.

The division of the metropolitan territory into districts, the manner and extent of the protection proposed for the waters of the harbor, and the cost of the drainage and disposal works will be the subjects of special reports to be submitted by this Commission as rapidly as the progress of the investigations permits.

Review and Conclusions.

Reviewing the various subjects dealt with in this report and combining the main facts and opinions for convenience of review, the following subjects seem to this Commission to be of special interest:

1. Although not necessary, it is within the range of engineering ability to collect all the sewage of the metropolitan district of New York and New Jersey to a central point for disposal.

2. The sewage of New Jersey, as well as that of New York, should be collected to a central point only in case the sewage is to be discharged at sea continuously and not exposed upon or above the surface of the ground.

8 3. It would not be desirable, from engineering considerations and on account of the cost, to discharge continuously all the sewage of the New York and New Jersey metropolitan district at sea, nor the sewage of New York at sea during all stages of tide.

4. The sewage of New York could be intermittently discharged at sea through tunnels, by employing storage basins and allowing the sewage to flow away on outgoing currents. The cost seems to make this plan prohibitive.

5. The sewage of New York could be carried to Long Island and disposed of on land, so far as engineering considerations are concerned, but the cost would not be justified.

6. The sewage of New York could be purified at one point so as to be inoffensive and without serious chance of harm to health. The works would cost what seems to be an excessively large amount of money.

7. The cost of collecting the sewage to one point and disposing of it intensively would be smaller than the cost of applying the sewage to land, but it would still be so great as to make the project appear to be inadvisable.

8. At some remote time, it may be necessary to collect all the sewage of New York to a central point for treatment or discharge at sea. This fact should be kept in mind in laying out such systems of main drainage and treatment as may be necessary for the present and near future.

9. The plan of collecting all the sewage to a central point seems to be unnecessary for the reason that other remedies, costing less money and involving fewer engineering and sanitary difficulties, appear to be more suitable. These remedies lie in dividing the City of New York into districts, determined chiefly by natural drainage areas, and providing main sewers and proper methods of disposal for each. The boundaries of these districts and the way in which this Commission proposes to deal with them will be the subject of future reports.

APPENDIX A.

Revised Estimates of Population and Sewage Flow.

The following revised estimates of population and sewage flow of New York City in 1940 were made after the results of the United States census enumeration of 1910 became available. This was subsequent to the publication of the report of the Metropolitan Sewerage Commission, dated April 30, 1910.

Population.

The estimated population of New York City in 1940, as given in the report of the Metropolitan Sewerage Commission, dated April 30, 1910, on page 144, was 8,666,100. This result was reached after a careful study of population data available at the time. From curves drawn to show the probable future growth of population in each of the boroughs from which this total was made up, the estimated population of the City in 1910 was found to be 4,600,000. The U. S. census of 1910 gave the population of New York City as 4,766,883, indicating that the actual rate of growth in the city had been somewhat greater than that assumed in the estimates made by the Commission.

In view of this fact, and after full consideration of the subject, it was decided to take 9,000,000 instead of the earlier estimate of 8,666,100 as the approximate population of New York City in 1940.

In Table 1 of this appendix will be found summarized by boroughs, the estimate of population of New York City in 1910, as made by

the Commission prior to April 30, 1910; the population as determined by the U. S. census in 1910; the estimated population in 1940 as made by the Commission prior to April 30, 1910, and the revised estimates of population in 1940, as made subsequently.

Volume of Sewage Flow.

The estimated volume of sewage flow of New York City in 1940, as given in the report of the Commission, page 146, was 1,580,000,000 gallons per 24 hours. Information obtained subsequent to the publication of the report made it seem advisable to reconsider this estimate and, as a result, new estimates were made. These gave 1,330,000,000 gallons per 24 hours as the total estimated volume of sewage flow of New York City in 1940.

The following facts led to the making of the new estimate:

1. Definite knowledge as to the population in New York City in 1910, the returns of the U. S. census of 1910 having become available.

2. More definite information as to the probable total water consumption and water consumption per capita in New York City in 1910, figures of the water consumption in 1909 having become available, from which, with definite knowledge as to population, a reasonably close estimate could be made of the probable water consumption in the City in 1910.

3. Figures from the Board of Water Supply giving their estimate of the future population and total water consumption in each of the boroughs of New York City in 1940.

In Tables 2, 3, 4 and 5 of this appendix are given the estimate of the volume of sewage flow in New York City in 1940 made by the Commission prior to April 30, 1910, the revised estimate made subsequent to April 30, 1910, the estimated water consumption in New York City in 1910 and the estimate of the population and water consumption in New York City in 1940 made by the Board of Water Supply.

12 APPENDIX B.

Discharge of New York's Sewage at Sea.

This project has for its aim the disposal at sea of all the sewage from New York City. The sewage would be collected by means of long, intercepting sewers all leading to one central point near Rockaway Inlet at the ocean entrance to New York harbor, where a pumping station and large retaining reservoirs would be located.

This project involves the discharge of the sewage intermittently at sea at a point about five miles southeast of Rockaway Point and during the first four hours of each outgoing tide. The sewage would be pumped continuously to the retaining reservoirs.

The estimated cost of the above project is $140,600,000. It would care for 1,330 million gallons of sewage per 24 hours. It is estimated that there will be a dry weather flow of sewage from a population of 9,000,000 persons in the year 1940.

The estimate of cost given above is, at the best, but a very rough approximation and should be considered only as such.

Sewers.

In order to carry the sewage to Barren Island, five main sewers would be built, as follows:

Richmond-Brooklyn Line.
Manhattan-Brooklyn Line (West).
Manhattan-Brooklyn Line (East).
Bronx-Queens-Brooklyn Line.
Queens-Brooklyn Line.

Pumping Stations.

In addition to a main pumping station near Rockaway Inlet, pumping stations would be required at one or more points on each of the five main sewers or their branches.

It is assumed that the maximum capacity of the pumps in each station would be 50% in excess of what may be termed the average capacity; in addition to this a reserve capacity has been provided.

Storage Reservoirs.

It is assumed that the sewage would be stored during a period of 8 hours and that the volume so stored would be discharged at
13 sea during the subsequent 4 hours, together with the sewage reaching the central pumping station during this latter period.

It is assumed that 50% of the average daily flow of 1,330 million gallons might reach the central station during a period of 8 hours. To store this volume of sewage, reservoirs having a capacity of 665 million gallons would be required.

With a depth of 20 feet, the reservoirs would have a net area of about 102 acres; allowing about 25% additional for walls embankments, pumping station, etc., or, say, 23 acres, the total area required at the sewage station would be about 125 acres.

Outfall Tunnels.

It would be very desirable, both on account of obtaining the most favorable conditions at the points of outlet and of minimizing the number of large and costly tunnels, to make both discharges of the day of equal volume without enlarging the capacity of the reservoirs beyond a size necessary to store the maximum flow for any 8-hour period of the day. By a proper method of operation this can be done, the conditions of pressure under which the two daily discharges take place being made very nearly the same. One-half the average daily sewage flow, or 365 million gallons, will therefore be outletted during each 4-hour period.

The average rate of discharge through the tunnels would be:

$665 \times 24/4 = 3,990$ million gallons per 24 hours.

To discharge at the above rate with a velocity of 6 feet per second, a tunnel capacity equivalent to that afforded by 4 tunnels 18′-0″ in diameter would be required.

The velocity at the beginning and ending of discharge would be 7.5 and 4.5 feet per second, respectively.

It is proposed that the tunnels discharge at a point about 3 miles north of the Ambrose Channel light vessel and about 5 miles southeast of Rockaway Point.

Estimates of Cost.

Land:		
In Richmond (Stapleton)	$40,000	
In Brooklyn (Red Hook)	250,000	
In Brooklyn (Navy Yard)	250,000	
In Queens (Steinway)	50,000	
In Queens (Flushing Creek)	5,000	
In Queens (Jamaico Bay)	5,000	
In Brooklyn (Barren Island)	1,250,000	
		$1,850,000
14 Sewers to Barren Island:		
Richmond-Brooklyn Line	$5,450,000	
Manhattan-Brooklyn Line (West)	12,500,000	
Manhattan-Brooklyn Line (East)	14,050,000	
Bronx-Queens-Brooklyn Line	13,650,000	
Queens-Brooklyn Line	4,350,000	
Allowance for Rockaway	1,000,000	
		$51,000,000

Pumping Stations:		
Richmond (Stapleton)	$461,000	
Brooklyn (Red Hook)	714,000	
Brooklyn (Navy Yard)	843,000	
Queens (Steinway)	587,000	
Queens (Flushing Creek)	814,000	
Queens (Jamaica Bay)	103,000	
Brooklyn (Barren Island)	8,040,000	
		$11,560,000
Storage Reservoirs		6,650,000
Outfall Tunnels		51,200,000
		$122,260,000
Engineering and Contingencies, 15%		18,340,000
Total		$140,600,000

15 APPENDIX C.

Disposal of New York's Sewage on Farm Land.

The estimated approximate cost of works for collecting the sewage of New York City, pumping it from Jamaica to, and disposing of it on, sewage farms on Long Island, but exclusive of the cost of land for the sewage farms, follows:

Land for pumping stations in New York City	$625,000
Sewers to main pumping station at Jamaica	51,000,000
Pumping stations in New York City	12,140,000
Gravity conduits, Jamaica to Massapequa	34,500,000
Pumping station at Massapequa	13,500,000
Force mains at Massapequa	10,000,000
Development of sewage farms	11,085,000
	$132,850,000
Engineering and contingencies, 15%	19,930,000
Total	$152,780,000

The main assumptions on which this estimate is based follow:

Works of Capacity Sufficient to Collect and Dispose of the Total Volume of Sewage (Dry Weather Flow Only) of New York City for the Year 1940:

Estimated population in 1940 9,000,000
Estimated mean sewage flow in 1940 .....1,330 mil. gals. per 24 hrs.

The estimated population and sewage flow of the city in 1940, by boroughs, the sewers leading to a main pumping station at Jamaica

and the requirements at the pumping stations in New York City, except the main one, are the same as those contained in Appendix B.

The estimate of cost given is, at the best, but a very rough approximation, and should be considered only as such.

16 APPENDIX D.

Intensive Purification of New York's Sewage.

The estimated approximate cost of works for collecting the sewage of New York City, carrying it to Barren Island, treating it there in Emscher tanks and percolating filters and then discharging it into Rockaway Inlet follows

Land	$4,700,000
Sewers to Barren Island	51,000,000
Pumping stations	12,140,000
Treatment works	49,900,000
Outfall works	5,000,000
	$122,740,000
Engineering and Contingencies, 15%	18,410,000
Total	$141,150,000

The main assumptions on which the estimate is based are as follows:

Works of Capacity Sufficient to Collect and Dispose of the Total Volume of Sewage (Dry Weather Flow Only) of New York City for the Year 1940.

Estimated population in 1940 9,000,000
Estimated mean sewage flow in 1940....1,330 mil. gals. per 24 hrs.

The estimated population and sewage flow of New York in 1940, by boroughs, the sewers leading to Barren Island, and the requirements at all the pumping stations, except the main one, are the same as those contained in Appendix B.

The estimate of cost given above is, at the best, but a very rough approximation, and should be considered only as such.

1 COMPLAINANTS' EXHIBIT No. 148. James D. Maher, Commissioner.

NEW YORK CITY, May 19, 1913.

This certifies that a copy of the within report has been filed in the Mayor's office by the Metropolitan Sewerage Commission.

JAMES MATTHEWS,
Executive Secretary.

Preliminary Reports on the Disposal of New York's Sewage.

II.

Description of the Four Principal Drainage Divisions in That Part of the Metropolitan Sewerage District Which Lies in New York State.*

Metropolitan Sewerage Commission of New York: George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sooysmith, Linsly R. Williams, Commissioners.

NOVEMBER, 1911.

2 *Description of the Four Principal Drainage Divisions in That Part of the Metropolitan Sewerage District Which Lies in New York State.*

Honorable William J. Gaynor, Mayor of the City of New York:

SIR: The studies of the Metropolitan Sewerage Commission from 1908 to 1910 covered a territory of about 720 square miles, about one-half of which lay in the State of New York and the other half in the State of New Jersey. This territory, which the commission outlined, called the Metropolitan Sewerage District, included all the important cities and towns situated on the shores of New York harbor and its immediate drainage areas.

The investigations were fully reported on in April, 1910, at which time the commission expected to go out of existence by statutory limitation.

The commission was continued by the Legislature in 1910 for three years in order that it might make plans and estimates of cost for such main drainage works for New York as its investigations had shown to be necessary. In the work done since April, 1910, the commission has confined itself to the study of main drainage works for that portion of the Metropolitan District which is within the State of New York.

*This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service. Some features of this report will remain open for revision until the final report is submitted.

Considerations Affecting the Division of the Territory.

In Preliminary Report No. I of the Metropolitan Sewerage Commission, dated September, 1911, wherein the feasibility of collecting all the sewage of New York to one central point for disposal was discussed, it was proposed that this authority should be separated into a number of divisions to facilitate the design of a system of main drainage, and in the report of this commission, dated April, 1910, wherein the necessity for this division was foreshadowed, it was suggested that the boundaries of these divisions should be determined partly by the quantities of sewage produced, partly by the facilities which were open in the several localities for disposing of the waste in a sanitary manner and partly by considerations of cost.

It is evident that a rational division of the territory should be based not only upon these considerations, but upon others There should be a due regard for the part of the harbor to be protected; its form, location, extent, depth and the volume of water passing; its uses for traffic, recreation, shellfish culture, bathing, etc., and for the present and probable future state of municipal development on its shores.

For purposes of administration, it was at first thought that the division of the territory should harmonize, if possible, with the separation of the city into boroughs, but a rigid agreement with borough boundaries was soon seen to be impracticable and unnecessary.

In separating the territory into main sewerage divisions, the chief consideration is to provide for an adequate and reasonably economical protection of the harbor water and to accomplish this by means of systems of large collecting sewers and well-situated central stations to which the sewage can be collected, and from which it can be discharged after the removal of more or less of its impurities.

The extent to which the harbor needs to be protected is of fundamental importance in these studies. The commission has found that it will not be necessary to keep all the sewage out of the harbor, for these waters can absorb a large amount of sewage harmlessly and inoffensively. The commission considers that this capacity should be fully utilized, and has undertaken to determine to what extent and in what ways this can be done. A report which will deal especially with the absorptive capacity of the harbor will soon be issued by the commission as Preliminary Report No. III.

The Four Divisions and Their Main Characteristics.

Keeping in mind the considerations which have affected the separation of the territory into divisions and remembering that sewerage systems must conform closely with natural drainage areas, it is easy to comprehend the method adopted by the Metropolitan Sewerage Commission in separating the territory into a number of main sewerage divisions. The drainage areas included within the principal watersheds have been laid down on a map and these areas have then been formed into a few large groups, depending upon the part of the harbor into which their drainage naturally discharged. Here-

after, these groups will be called, by this commission, divisions, and the separate drainage areas within them for which a system of main drainage is designed, leading to a separate outlet, will be termed sub-divisions.

It seems best to designate the several main sewerage divisions according to the parts of the harbor which they were to protect and the subdivisions by a name which will sufficiently indicate the location.

The territory whose drainage flows, or can readily be made to flow, into Jamaica bay is called the Jamaica bay Division.

4 The territory in the Borough of Richmond, or, as it is more generally termed, Staten Island, constitutes the Richmond Division.

The territory on Manhattan Island and in Brooklyn which drains into the Lower East and Lower Hudson rivers and Upper bay constitutes the Lower Hudson river, Lower East river and Bay Divisions.

The territory in the Borough of Northern Queens, in the Borough of The Bronx which naturally drains into the Upper East river, and that part of the Borough of Manhattan and the Borough of The Bronx which naturally drains into the Harlem river constitutes the Upper East river and Harlem Division.

A fuller description of these divisions will be given further on in this report.

The four divisions are markedly dissimilar in topography, density of population and in location with respect to the ocean and to large volumes of swiftly running tidal water, yet the range of main drainage and of sewage disposal problems is not great in each.

The subjects of controlling importance in each division are the opportunities and obstacles which they afford for the discharge of the sewage with a minimum amount of treatment and without producing conditions injurious to the public health and welfare.

The Selection of Central Points for Disposal.

Having tentatively settled upon the main divisions into which it is desirable to divide the territory, the selection of central points to which the sewage can be collected for treatment and disposal became a matter of the utmost importance. Upon the choice of these points depends not only the cost of collecting the sewage, but the method of treating it and the facility with which it can be disposed of after treatment.

It is considered by the commission that as far as practicable, the collecting points should be near the ocean or Long Island sound or close to the unobstructed flow in deep, tidal channels. Points of outlet for untreated sewage should never be situated in shallow, stagnant or remote parts of the harbor. When these favorable conditions cannot be secured, an approach to them should be sought. At any outfall where facilities are lacking for the disposal of the sewage through dilution by large volumes of freely-flowing tidal water, compensation for this lack should be made by a higher degree of treatment for the removal of impurities before the sewage is discharged.

5 It is considered desirable to reduce the number of central points as far as practicable in order to facilitate the ultimate disposal of the sewage, due attention being given to the probability that pumping will have to be employed to some extent and to the fact that for purposes of administration, the works should be concentrated as much as is consistent with due regard to first cost.

The exact degree of purification required for the sewage cannot, at this time, be stated, but an effort should be made to avoid elaborate processes which will require much land and expensive plants and involve large cost for maintenance. The aim should be to make good use of the absorptive capacity of the harbor waters. By good use is meant such use as will do no material harm to the public health and welfare either by producing disease or causing nuisance. In exceptional cases the utmost degree of purification obtainable may be necessary.

Work on the Definite Plans and Estimates.

In making the plans and estimates of cost of the main drainage works for the several divisions of the territory it has been considered by no means necessary that all the lines and grades and sizes shall be finally and exactly fixed. At the same time, it is evident that the outcome of the commission's studies should possess definiteness and take account of the ascertainable conditions of population and topography. For this reason, investigations have been undertaken and efforts made to obtain from the local sewer bureaus, topographical bureaus, and elsewhere, such necessary data as were available and to base upon these carefully considered plans for each division.

The plans which will be the result of this work are to be regarded as the outcome of careful studies based on the outlook in the year 1911 for the municipal development of the region under consideration, and on the existing state of the art of sewage disposal. All the work planned will not be needed in the immediate future, but it is regarded as essential that such main drainage works as are undertaken should in general conform to these plans and be made part of the general scheme.

The possibility that a more complete system of protecting the waters than that outlined here may be needed in the distant future is being kept in mind in preparing the plans. It is believed by the commission that if greater protection is needed, it can be secured by extending the treatment works which the commission will propose, without undue sacrifice of any part of completed structures.

In designing the main drainage works, careful account will be taken of the character of sewers, where any sewers exist. Most
6 of the sewers already constructed by the city were built to accommodate house, factory and storm water drainage. Where no sewers have been built or have been designed, and a separate system seems to the commission the more suitable, it will be assumed that a separate system will be constructed and provisions will be made in the plans for sewage collected in this way.

Jamaica Bay Division.

The Jamaica Bay Division faces directly upon the Atlantic ocean; it is in little danger of being affected by the drainage of the rest of the City; and the disposal of its sewage is likely to have little or no effect upon the other divisions.

This division is bounded by a natural ridge, which begins at Bensonhurst, Gravesend Bay, runs in a general northeasterly direction to the easterly boundary of New York City near Lake Surprise, continues to a point just west of Roslyn, bends south and extends to Lynbrook, from which it follows the height of land along the Rockaway peninsula to the City line and the ocean.

The Jamaica Bay Division covers a total area of about 103 square miles. Of this, about 76 are land and 27 water or low-lying marshy islands.

The bay is very shallow except in its southwestern part, where a deep channel enters from the ocean and, dividing into numerous branches, flows among the islands.

The refreshing action which the tide produces upon the bay is large, for although the currents do not flow in one direction (the most advantageous from the point of view of ordinary flushing), the bay is so shallow that a large proportion of its water leaves at each falling tide, and is replaced as the tide rises. Calculation shows that the bay half empties itself at each tide. The volume of water contained at low water is estimated to be 2,400 million cubic feet, and the mean tidal prism 2,000 million cubic feet. The large area of the water surface, as compared with the shallow depth, is favorable to the absorption of oxygen from the atmosphere and to a thorough commingling of the waters, two conditions which favor the bay as a place for the harmless and inoffensive assimilation of sewage matters.

On the other hand, there are large areas of bottom exposed at low tide which would become very offensive if polluted by sewage. The extensive shallow parts of the bay support dense growths of vegetable matter which, decomposing, sometimes place a considerable burden upon the dissolved oxygen which the water contains. Probably four-fifths of the bottom is covered with black mud in which vegetable and animal organisms in great variety exist. The mud varies in consistency from a tough, dense, clayey mass to a light ooze. It is always black and generally putrefactive. The odors which now arise from the mud are such as are commonly noticeable at the sea-side, and are not generally objected to.

Clams, both the soft shell, Mya arenaria, and the hard shell, Venus mercenaria, grow luxuriantly, and are taken from the waters in large numbers. Soft shell clams are in places taken under circumstances which lead to the opinion that they are polluted.

Oysters are planted extensively on the harder bottoms near the sides of the main channels in the southwestern part of the bay. The oysters grow well and command good prices in the market. Many are eaten raw, although the typical oysters from this vicinity, formerly known as Rockaways, were large and generally used for cooking.

Fish do not enter Jamaica bay from the ocean except in small numbers and at certain seasons of year, although the fishing a few miles outside of the inlet is usually excellent. A numerous fleet of fishing boats with headquarters inside the bay is constantly engaged in angling in the ocean.

Much of the territory included in the Jamaica Bay Division is in a state of transition from open, rural country to built-up city conditions. Close along the southern shore and two miles and more from the northern shore are extensive sections which possess the characteristic features of permanent development. The territory in the northeast is sparsely settled.

It has been proposed by the City of New York and National Government to construct extensive engineering works to convert Jamaica bay into a safe and convenient harbor for ocean-going vessels and, if this is done, as now appears likely, the natural characteristics of the bay will, in a large part, give place to deeper, straighter, wider channels, canals and bulkheaded shores.

The total population of the Jamaica Bay Division was, in the year 1910, about 366,000. The population is growing rapidly and is expected to reach about 1,548,500 in 1950 or 1960.

Sewage now enters the bay from a few large sewers on the northern and western shores and from many small outlets on the south. The large sewers are mostly connected with sewage disposal works designed to operate on the principle of chemical precipitation. These works are all inefficient and have repeatedly been criticised adversely by and for the Bureaus of Sewers of the boroughs in which they are situated.

8 Richmond Division.

The Richmond Division includes the whole of Staten Island. The total area of land is about 57 square miles of which about one sixth is marsh.

Staten Island is, in part, rough, high and hilly and, in part, low-lying and flat. Except at the northern end, the low land lies near the shores. The high parts of the island lie along a broad ridge which extends in a northeasterly and southwesterly direction at a distance of from two to four miles from the shores of Lower New York bay.

The waters of Lower New York bay are shallow for a long distance seaward from the Staten Island shore. On this account, and for the reason that this shore is comparatively inaccessible by land transportation, and because of the exposure of this part of the island to the open sea, it seems likely that commercial development of this water front will long remain dormant as now. The south shore is now occupied largely by summer residents and by permanent settlers who live in small villages near the foot of the hills. There are several extensively patronized bathing beaches on the south shore of Staten Island. The west side of the island, bordered by the Arthur Kill, has been developed to some extent for manufacturing, but land values here have not advanced as rapidly as might be ex-

pected, apparently, because much of the land consists of salt meadows.

The principal residence and business parts of the Richmond Division lie at the north end of the island. Here numerous large towns are situated, each fronting on Upper New York bay or the Kill von Kull and bordered on the other sides by other towns or the open country. The business done is chiefly manufacturing and maritime and is carried on close to the water's edge.

At the present time, 1911, the population of Staten Island is about 90,000. The towns are partly sewered and in many cases the sewers are on the combined plan. There are about 30 outlets from which sewage is discharged without treatment into the nearest large body of water. It is certain that the population of Staten Island will increase for many years and that this territory will continue to grow with the rest of New York. Up to the present time, this division has not benefited to the extent which might be expected from its excellent position and other natural advantages.

Lower Hudson, Lower East River and Bay Division.

The greatest part of the most densely settled portion of New York City is included in the Lower Hudson, Lower East River and
9 Bay Division. This division includes all of the Borough of Manhattan except that portion at the northeastern end which naturally drains into the Harlem river; all of the Borough of Brooklyn except that part which naturally drains into Jamaica Bay, and the eastern end of Gravesend bay; and that part of the Borough of Queens which naturally drains into the East river south of Lawrence Point near Hell Gate. To the southeast lies the Jamaica Bay Division, to the northeast the Upper East River and Harlem Division and to the southwest the Richmond Division.

The Lower Hudson, Lower East River and Bay Division affords serious obstacles to the design of sewerage works on account of the very large quantities of sewage to be dealt with, the absence of low-cost land and because of the slight elevation of the shores above tide water. Nearly all of the extensive shore line is low-lying and flat. Much of the originally indented shore has been filled in so that the water-front now appears upon the map to be remarkably smooth and uniform. The average tidal range is 4.4 near the center of the division.

Practically the whole division is now thoroughly sewered on the combined plan. The sewers discharge near the level of low tide and, except in the Borough of Manhattan, usually at the bulkhead or shore line. The sewers of Manhattan are, for the most part, carried out nearly to the outer ends of the piers which project perpendicularly from the shores at frequent intervals.

More than half of the land in the Lower Hudson, Lower East River and Harlem Division is built up in the compact manner characteristic of the most thickly settled parts of great cities. The other half is rapidly becoming permanently settled.

The Boroughs of Manhattan and Brooklyn, besides being great

residence centers, contain a large part of the industrial establishments which make New York the leading manufacturing center of the United States.

The total population of the Lower Hudson, Lower East River and Bay division was in 1910 about 3,230,000. It is estimated that this population will be 5,560,000 by 1940.

There are about 200 sewer outlets in this division.

The waters into which the crude sewage of this division is now discharged are those arms of the harbor from which the division takes its name. The Hudson is a broad, deep waterway, capable of accommodating large sea going vessels at any point between its shores from its mouth at the junction with the Upper bay to a point near the northern limit of the Metropolitan Sewerage District, except on the New Jersey side, which is somewhat shallow, undeveloped and difficult for land transportation, from a point about four miles above the mouth of the river and running north.

Upper New York bay, while deep in the main channels, contains extensive shoals on its east and west sides. The shallow flats on the west side of the bay are noteworthy in this respect, for they underlie about one-third of the entire water surface at depths of from 2 to 10 feet below low tide. The shoal on the east side of the bay extends for a distance of about 3 miles, and is overlaid by about 15 feet of water at low tide.

The Lower East river joins Upper New York bay close to the mouth of the Hudson. The East river is narrower and swifter than the Hudson, but of about the same depth. The East river is in reality a strait which joins Upper New York bay with Long Island sound. Sea-going vessels can traverse any part of the Lower East river, and reach any of its docks and piers.

These three large sections of the harbor, the Lower Hudson, Lower East river and Upper bay have some features in common and some differences which it is desirable to keep in mind in considering the question of a sanitary disposal of the sewage. The tidal range is practically the same. Under ordinary circumstances, practically the same water circulates back and forth in the bay, East river and Hudson river, which together may be likened to the stem and arms of the capital letter Y. At dry seasons of the year there is comparatively little net movement of the water to sea. After continued heavy rains the Hudson discharges a heavy flow of water from the land. The discharge of the Hudson at times of storm produces effects which are plainly visible throughout the Lower East river and Upper bay. There is marked change in the color and turbidity of the water. The change is sudden; the effects wear away slowly. Normally the water is of an olive green and slightly turbid appearance.

Upper East River and Harlem Division.

The Upper East River and Harlem Division includes nearly the whole of the Borough of The Bronx, that part of Manhattan Island

which naturally drains to the Harlem river, and that part of the Borough of Queens, whose natural drainage flows to the East river, east of Lawrence Point near Hell Gate.

The topography and municipal development of this division is various in the extreme. The elevation of land in the western part of The Bronx is high, the Harlem river flowing for part of its way between steep banks. To the east, steep, narrow valleys run between parallel ridges in a north and south direction, the land gradually becoming more uniform in contour eastwardly.

11 The topography of that part of this division which lies in Queens is notable for its sloping land, situated at a considerable elevation, and its extensive low-lying tidal meadows opening into the East river.

Both sides of the Upper East river are characterized by elevated promontories and deeply placed bays. The bays are all very shallow and their bottoms are covered with black mud. A natural channel suitable for vessels drawing not over 24 feet of water runs between the headlands throughout the length of this part of the river.

Flushing bay is the most notable example of the numerous shallow estuaries which open into the river. This bay, which is about a mile and a quarter wide at its junction with the East river has, with the tidal meadows at its head, a tidal length of 5 miles. Shallow water extends from the mouth of this bay for a mile and a half. The East river itself is about a mile and a half wide just east of the mouth of Flushing bay. It is important to note the physical conditions of these bays and of the extensive low-lying meadow lands at their heads, for these conditions have important bearings on the problem of sewage disposal. They make the sewage more difficult both to collect and to dispose of.

The ship channel through the Upper East river is narrower than the channel in the Hudson or Lower East river and less deep, but the rise and fall of tide are somewhat greater. The incoming tide which comes in from the ocean by way of the Upper bay meets that which comes in by way of the sound in the Upper East river, a fact which gives to this arm of the harbor considerable hydrographic interest and has some bearing on the problem of sewage disposal.

The Harlem river joins the Hudson with the East river and forms the northern boundary of Manhattan. This stream is narrow and shallow compared with the other main parts of the harbor, its present use being largely confined to a small amount of shipping. At the southern end, the shores of the Harlem are closely occupied, *which* the remainder is largely unimproved.

Municipal conditions vary widely in this division. There is an area of several square miles in the southwestern part of The Bronx which is almost as densely settled as any part of the City of New York, and there are parts of Queens which possess every semblance of rural remoteness. That part of Manhattan which is comprised in this division includes a section which is said to be occupied by the most densely congested population in the world.

In a large part of this division, rural and semi-rural conditions exist. Isolated towns with large residence populations are growing

and will doubtless ultimately converge, while new centers are constantly being established through the efforts of enterprising real estate operators. The present population (1910) of this
12 division was about 1,103,000. By 1940 it is expected that the population will be 2,400,000.

The present number of sewer outlets in this division is about 86. Nearly all the sewers are constructed on the combined plan. There are many large collecting or trunk sewers already built and others contemplated.

Respectfully submitted,

METROPOLITAN SEWERAGE COMMISSION OF NEW YORK.

Preliminary Reports on the Disposal of New York's Sewage.

III.

Study of the Collection and Disposal of the Sewage of the Jamaica Bay Division.*

Metropolitan Sewerage Commission of New York.

George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sopysmith, Linsly R. Williams, Commissioners.

November, 1911.

NEW YORK CITY, May 19th, 1913.

This certifies that a copy of the within report has been filed in the Mayor's office by the Metropolitan Sewerage Commission.

JAMES MATTHEWS,
Executive Secretary.

1 Study of the Collection and Disposal of the Sewage of the Jamaica Bay Division.

December 2, 1911.

Honorable William J. Gaynor, Mayor of the City of New York.

SIR: Following is a report upon a general plan of main drainage and sewage disposal for part of the Boroughs of Brooklyn and Queens whose natural drainage flows into Jamaica Bay.

The design herein embodied is the result of careful study based on the outlook in the year 1912 for the municipal development of the region under consideration and on the existing state of the art of sewage disposal.

All the work planned will not be required in the immediate future, but it is regarded as necessary that such main drainage work as is undertaken by the city should conform to these plans, or such modifications of them as may be determined upon. The possibility that a more complete system of main drainage than that here proposed may be needed in the very distant future has been kept in mind in preparing these plans, and it is believed that the works can be adopted so as to afford a more thorough protection of the harbor, if that is ultimately needed.

---

*This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service. Some features of this report will remain open for revision until the final report is submitted.

Boundaries of the Division.

As proposed in Preliminary Report No. 1, of the Metropolitan Sewerage Commission, dated September, 1911, the Commission has separated the City of New York into a number of divisions to facilitate the design of a system of main drainage for the protection of the harbor waters against sewage pollution. The principal divisions are five in number, and take their names from the waters into which their natural drainage discharges.

The territory included in the Jamaica Bay division lies in the southeastern part of the City of New York.

The division is bounded by an irregular line following the watershed from 23d Avenue and Gravesend Bay, Borough of Brooklyn, to a point about three-quarters of a mile east of Prospect Park, thence northeasterly to the easterly boundary of New York City near Creedmoor, thence southerly following the city boundary to the ocean. The total area of land to bulkhead line is about
2 83.8 square miles. Of this area about 35.5 square miles lie in Brooklyn and 48.3 in Queens.

General Features of the Division.

The principal topographical features of this division include a natural ridge, which forms the northern boundary of the territory, and from which the land slopes gradually to low-lying tidal meadows; the large, shallow expanse of Jamaica Bay, studded with numerous marshy islands and hummocks, intercepted with narrow, crooked channels; and, finally, a protective barrier formed by the low, sandy shore of the Rockaway peninsula, separating the bay and the rest of the division from the open waters of the Atlantic Ocean. In places, the low-lying meadows to the north of the bay extend for over two miles. Back of the meadows, the upland begins and runs in a slightly elevated tract which rises, on an average, 4 or 5 feet per thousand, until near the northern boundary of the division, where the elevation increases more rapidly.

The Jamaica Bay division is partly built up. Parts of it include a thickly settled district in Brooklyn, parts consist of separated country villages, parts of strictly rural territory, including farms, and parts of large stretches of unprofitable salt marshes. Finally, there are some largely attended day summer resorts.

The population of the whole territory in 1910 was about 366,000, including 13,000 residents of Brooklyn, now draining to Gravesend Bay, which it is proposed to include in the Jamaica Bay system. The density of settlement, as shown by dividing the population by the area, gives but a poor idea of the extent to which the division is settled, for the reason that there are large, unpopulated sections and some rather densely peopled parts. The density thus divisionally determined varies between sixty persons per acre, at a point in Brooklyn, to one in ten acres near the head of Jamaica Bay in Queens.

Probable Future of Jamaica Bay.

Coney Island and Rockaway Beach, each of which is visited by hundreds of thousands of visitors on a summer holiday, are in this division. Parts of the division have increased largely in population during recent years and are still growing rapidly under the fostering operations of real estate operators.

The shores of the bay are now devoted almost exclusively to the uses of a transient summer population and the waters to sailing, bathing and the cultivation of shell fish.

The shell fish interests of Jamaica Bay are extensive. These waters, which first became famous for oyster culture about
3 fifty years ago, are now much used for growing oysters and hard and soft shell clams. The beds are located on the bottom and sides of the natural main channels. The future development of the bay will make shell fish culture unsafe from the standpoint of disease.

Unlike the cultivation of oysters and hard shell clams, which is carried on by means of seed brought from elsewhere, the muddy shores of Jamaica Bay afford seemingly endless supplies of soft shell clams. These clams are free to any one who will gather them. Persons may be seen digging soft clams in practically all parts of Jamaica Bay during low tides.

In summer hundreds of small boats ply the waters on Sundays and holidays and the water front in those parts of the bay which are most easily accessible are settled with crowded communities which live in tents and cottages of an inexpensive nature.

The future of this division is uncertain, although there is a definite plan for the development of Jamaica Bay for commercial purposes. This plan, which was proposed by a special body created for the purpose, and known as the Jamaica Bay Improvement Commission, involves extensive engineering works. It is proposed to construct a substantial and regular shore line, deep, wide channels for ocean-going vessels, and harbor approaches for the entrance at Jamaica inlet.

It is also proposed to construct a number of canals on the northern shore, each about 300 or 400 feet in width and from 4,500 to 12,000 feet long, extending back into the territory at places where natural creeks exist, so as to increase the water front. The object of this development is to increase the shipping facilities of New York by providing additional wharves, storehouses, terminal facilities and space for the handling of vessels. At the present time no business of this kind exists, or is possible, in Jamaica Bay, owing to the shallowness of the water, lack of railroad facilities and store-house accommodations.

As to the future of the beaches known as Coney Island and Rockaway, it seems likely that they will long remain pleasure resorts, in spite of any commercial development which will occur in the neighborhood. The situation of Coney Island makes it comparatively remote from the shipping centers and the ocean front of Rockaway

Beach renders it, to a considerable extent, independent of the natural resources of Jamaica Bay which commercial conditions may destroy.

It is necessary to carefully consider how the waters of Jamaica Bay are now used or are likely to be used in future in order to determine the degree of thoroughness with which these waters are to be protected from sewage pollution. If the waters are to be kept pure enough for bathing, boating and shellfish culture, a different method of dealing with the sewage disposal problem of this division should be followed than if the bay is to be devoted to commercial purposes.

4

From a careful study of the Jamaica Bay Improvement Commission's reports, it seems improbable that the waters of this division could be used both for shipping and the other purposes to which they are now put. The development of the bay for commerce would seem necessarily to exclude its use for pleasure; and, conversely, if the bay is to be maintained for purposes of recreation, its value will be seriously impaired by the developments of commerce. So far as the Metropolitan Sewerage Commission can foresee, the future of Jamaica Bay will lie along the lines proposed by the Jamaica Bay Improvement Commission. It appears that an agreement to develop this harbor for shipping has been entered into between the U. S. Government and the City of New York, that outline plans have been officially adopted and money appropriated to begin the work.

That the development of the area draining to Jamaica Bay will be rapid, probably will not be disputed. The chief causes for this are: First, the improvements recently made, and those in contemplation, by the Long Island Railroad Co. and by the Brooklyn Rapid Transit Co.; and secondly, Jamaica is probably destined to be of considerable importance as the local focus of railroad lines to all parts of Long Island—to the west by the Pennsylvania tunnels and to New England by the projected bridge across the East River near Hell Gate. Already large sums of money have been appropriated for improvements in this vicinity.

The effect of this development will be felt all along the main line of the branch of the Long Island Railroad, which extends east and west near the northern limit of the Jamaica Bay Division. The rapid transit lines and the southern branches of the Long Island Railroad will afford quick transportation from nearly all points in the drainage area to Brooklyn and Manhattan.

The projected Jamaica Bay Improvement, already mentioned, will provide economical entrance for coastwise and inland shipping. Building material can be delivered by water at low shipping rates, stimulating improvements on large areas accessible to the water front, which now are unoccupied and of little value.

It has been proposed to establish a barge canal terminal in Jamaica Bay. The length of water front and the large marginal areas available cannot be found elsewhere. The trip from Norton Point to Rockaway Point via the ocean can be obviated by the construction of the Gravesend ship canal, which is understood to be included in the project for this section of Brooklyn that has been adopted by the city authorities.

5 **Probable Future Population of the Division.**

In planning for the main drainage of this division, it has not seemed best to attempt to anticipate conditions more than 40 or 50 years in advance of the present time, for the reason that conditions may arise which will result in an increase or shifting of population quite different from any that can now be foreseen. A material variation from forecast population is more to be expected in the thinly populated and rapidly improving areas than in those where, as in much of the Brooklyn area, populations are dense and the conditions which affect growth are well established. For this reason, estimates for sewerage have been based upon a population in the Brooklyn portion of this division as forecasted for 1960, while in Queens the populations are forecasted for 1950.

The expected populations are, for the area lying in

Brooklyn	884,100
Queens	531,600
Total population planned for	1,415,700

General Outline of the Proposed Plan.

An outline of the plan which is being worked out follows:

The sewage is to be collected by the separate system, so far as possible. Where this is not feasible, the sewage provided for is confined to the dry weather flow. Allowance is made for an unavoidable inflow of ground water.

Where sewers have been constructed on the combined plan, it is proposed to intercept the dry-weather flow and provide storm water overflows above the points of interception. In this way a certain amount of house sewage mixed with storm water will pass to the bay during storms, but the amount which will enter in this way will be so small in comparison with the diluting water, that no objectionable conditions are to be apprehended from this cause.

A serious consideration is the street filth and grit which will be carried down with the surface water. This might seriously pollute and form deposits in the bay. The dissolved organic matter will be taken care of by the large volume of water with which it will be diluted, but the floating solids and grit should be removed by screening and grit chambers placed near the outlets of the more important storm water drains.

The projected long canals mentioned earlier in this report will be most difficult to maintain in an unpolluted condition. There will be but little flow through them and practically no flushing effect 6 from the tides. These long canals may become nuisances similar to Gowanus Canal and Newtown Creek, unless proper measures are taken to protect them.

The entire area can be divided into two subdivisions termed respectively the Eastern Jamaica subdivision and the Western Jamaica subdivision. Each will have a distinct system of collection and disposal.

The Western Jamaica subdivision will be the larger. It will collect the sewage from a population of 1,192,400 in 1960, located on about 49 square miles lying north of Jamaica Bay and west of Cornell Creek, and east of Ulmer Park. The sewage from this territory may be expected to amount to as much as 166 million gallons per day in 1960. It will be delivered to a pumping station to be located near Flatlash Avenue and Avenue X. From this point it will be pumped through force mains to Barren Island, where it will be treated, and the effluent discharged through submerged outlets into Rockaway inlet.

In the Eastern Jamaica subdivision there will be about 38 million gallons of sewage collected daily in 1950. This will be from a population of 223,300 on the 27.4 square miles of Queens, which lie to the southeast of Cornell Creek. This Eastern Jamaica sub-division is divided into two separate areas by Nassau County, which borders the head of the bay, the sewage from which is collected separately but carried to a common treatment plant on Jo Cos Marsh. The northerly area is expected to contribute 21.6 million gallons of sewage per day from a population of 111,800 distributed over 19.6 sq. mi. of territory, while the southerly area, comprising Far Rockaway and the Rockaway peninsula, is expected to contribute 16.5 million gallons per day from a population of 111,500 on 7.8 sq. mi.

From the northerly area the sewage will be brought to a pumping station near the Rockaway turnpike and Springfield road; and on the southerly area collecting sewers from the east and west will collect the sewage to a pumping station near Rockaway boulevard and Lucia avenue, Edgemere. From the pumping stations the entire volume will be pumped through submerged mains to a plant where the sewage will be treated on Jo Cos marsh. The effluent will be discharged into Broad channel.

The operation of the treatment works to be located at Barren Island and Jo Cos marsh will be restricted to house sewage, with such manufacturing wastes as it may be found best to admit into the sewers.

Western Jamaica Subdivision.

It is intended that the intercepting sewer of this subdivision, called the Flatlands-Jamaica interceptor, shall start with a diameter of 5' 4" in the Old South road north of the present Jamaica Disposal Works. It will pass under the sewer from Jamaica and intercept the sewage from that division.

7 The sewage from the low-lying area to the south will be collected at the present disposal works for Jamaica. This station will then be converted into a pumping plant, and the sewage will be pumped into the interceptor. At Panama Street the intercepting sewer passes under the Panama Street sewers; then under the Brooklyn aqueduct, the location of which controls the elevation of the interceptor. At the borough line and Cozine Street the diameter is to be 8' 6". The sewage collected at the present East New York disposal plant is to be lifted into the interceptor in Vandalia Avenue.

Assuming that Fresh Creek will be dredged for purposes of naviga-

tion, it will be best to cross under the creek by a siphon rather than carry the interceptor by a long detour around the head of the proposed basin.

At the head of Paerdegat basin, as well as at Hendrix Street, the existing storm drains will pass over without interfering with the flow by depressing the arch of the interceptor, but the domestic sewage collected at this point will have to be pumped into the interceptor. On Avenue T, between Ralph Street and Flatbush Avenue, the diameter is to be 14′ 4″. The invert is to be about 16′ below mean tide level.

At Avenue V and 11th Street, Bensonhurst, a pumping station is now being built to pump the sewage of the neighborhood to the 92d Street outlet near The Narrows. The sewer leading to this outlet eventually will be too small and it is proposed to divert this sewage by means of a sewer, called the Gravesend interceptor, to the east when conditions require the change. The sewers will increase from 4′ 9″ to 7′ 3″ diameter, and meet the interceptor from Jamaica at Flatbush Avenue. The present Coney Island sewage disposal plants will be abandoned or utilized as pumping stations, delivering sewage to pumps to be installed at Ocean Parkway, near Avenue W. The sewage delivered to the pumps at the present Shellbank Creek plant will be pumped to the interceptor.

From Avenue T the sewage will flow through twin sewers about 10′ 3″ square to the main pumping station. Here centrifugal pumps of capacity to lift 350 million gallons per day 35 feet will be installed. This is the only pumping station required on the line of the interceptors. Two 7′ 2″ force mains will then convey the sewage to the disposal plant at Barren Island.

Barren Island will probably be found to be a most suitable point at which to treat and dispose of the sewage. The sewage will be carried to this point by what is called the Barren Island force main. The area of land here is ample; the land belongs to the city; garbage reduction works are already located there; there are no residences in the vicinity except for the workmen employed at the reduction plant; the land is of suitable elevation and believed to furnish, below the surface mud, good material for foundations; it is accessible for transportation by water; on the south it forms one shore of Rockaway inlet, which, on account of its depth, swift currents and proximity to the ocean, furnishes an admirable body of water into which to discharge the effluent.

The degree of purification that will be required is not known at this time. A rough computation indicates that if all the sewage which would naturally drain to Jamaica Bay by 1960 were thoroughly diffused therein, the sewage would, under ordinary conditions, be diluted by about 147 volumes of water at times of low tide. This would be about six to seven times the amount of theoretical dilution required to provide sufficient oxygen to digest the organic matter during the summer months, the most unfavorable of the year.

As this ideal condition cannot be relied upon, treatment to remove the grosser solids and a certain part of the dissolved impurities must ultimately be provided. In order to show approximately the cost of

the masonry works when this territory shall have become occupied to the extent above described, it is assumed that the sewage will then have to be subjected to clarification in settling tanks and further treatment by sprinkling filters and settling basins. About 100 acres of land will be ultimately required for the entire plant.

The effluent from the plant will flow through four submerged pipe lines and discharge in the deep water of Rockaway inlet. The inoffensive sludge from the settling tanks can be used for many years to fill in marsh lands near the plant, or, if preferred, it can be dumped at sea.

The estimated cost of construction of this system for the full future estimated population is:

Interceptors	75,450	lin. ft.	$4,321,600
Siphons	1,150	" "	77,600
Pumping stations	5	" "	755,600
Force mains	9,400	" "	356,200
Treatment plant	.....		4,623,100
Outfall pipes	3,000	" "	154,150
Contingencies	15%		1,541,600
Total cost			$11,850,000

This sum need not all be expended at once, but those portions built should be in accordance with the complete plan, so far as practicable. The construction of some parts of the pumping plants, siphons, treatment plant and outlet pipes can be deferred for many years.

The area now draining to Paerdegat and the 26th Ward and Jamaica disposal plants require immediate relief. This relief will probably have to be met in part by temporary measures. It is desirable that plans for this portion of the interceptor leading to Barren Island be prepared and the work constructed at the earliest opportunity.

9

Eastern Jamaica Subdivision.

The northern or Springfield collector starts at the intersection of the Herrick Plank road and Springfield road with a size of 2' 2" x 3' 3" and runs southerly through Springfield to the Rockaway turnpike, where the diameter is 4' 6". Here there will be a pumping station provided with centrifugal pumps of sufficient capacity to lift 40 million gallons per day 77 feet. The sewage of the entire subdistrict will thus be conveyed across the intervening marshes and under the proposed channel for navigation to the Jo Cos Marsh disposal plant through a force main 33" in diameter, called the Springfield force main.

The Rockaway collector will start with a diameter 21" near Belle harbor, where it will receive the sewage from Rockaway park and the west from a pumping station located near Fifth and Newport avenues.

Running easterly along Rockaway boulevard, with pumping stations at Seaside, Hammels and Arverne, it will reach, with a diameter

of 45", a main pumping station at Edgemere. On the east, sewage collecting at the present Far Rockaway disposal plant will be pumped through a 12" cast-iron force main to Mott avenue and Sheridan boulevard from which a gravity collector, increasing in size from 30 to 36 inches, will run to the Edgemere pumping station. At Channel avenue this collector receives, from a 12" force main, the sewage collecting to the existing ejector station near Ocean and Channel avenues.

The Edgemere pumping station will be provided with centrifugal pumps of capacity to lift 30 million gallons per day 40 feet. The sewage of the entire southern sub-district will thus be carried by a 30-inch force main to Jo Cos Marsh, crossing under the proposed channel for navigation on the way, and called the Rockaway force main.

Jo Cos Marsh has been selected as a suitable location for treatment works, as it is at present waste land and centrally located with reference to the drainage area. It is, at the same time, a good distance from improved property. Finally, it is adjacent to the junction of Hassock Creek and Broad Channel which provide as favorable conditions for dilution as are to be had at the upper end of the bay. The currents depend largely, however, upon the wind. The oscillations of the tide are not sufficient to dispose of a large volume of putrescible sewage. The plan provides for the sewage to be given thorough treatment by settling tanks, sprinkling filters and settling basins. The works will cover about 30 acres of ground by 1950.

The effluent will be conveyed by two outlet pipes 42" in diameter, one to Hassock Creek and one to Broad Channel. The sludge can be used to fill marsh lands or it can be dumped at sea.

The estimated cost of construction of this system for the full estimated future population is as follows:

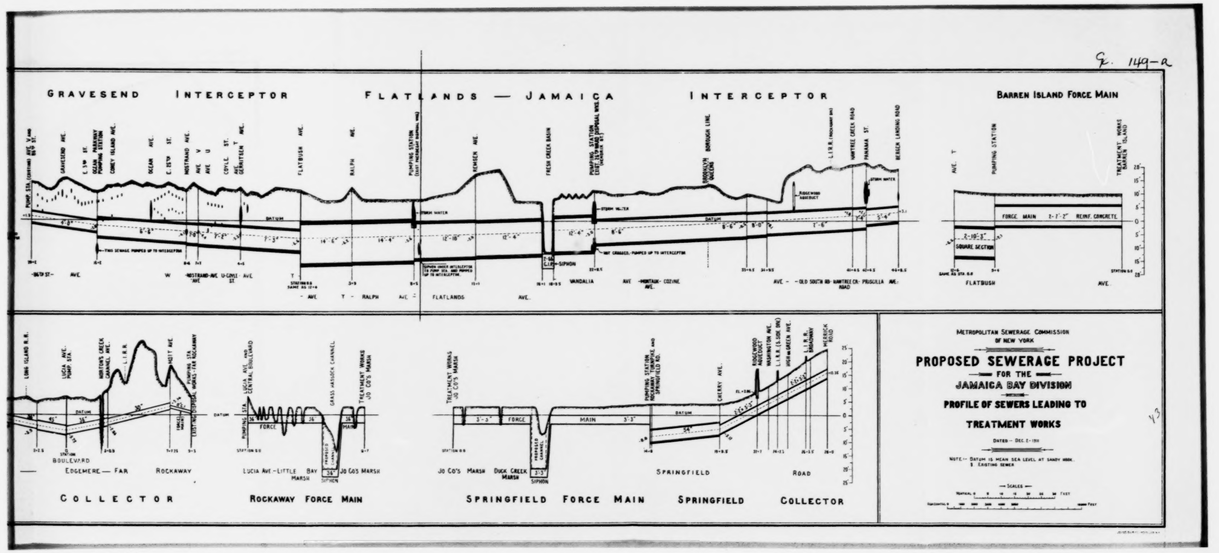
Interceptors	40,025	lin. ft.	$511,000
Pumping stations	7		79,996
Force mains	25,725	" "	330,070
Treatment plant	.....		1,061,340
Outfall pipes	3,900		90,600
Contingencies	15%		310,990
Total cost			$2,383,000

Much of the cost can be deferred for an indefinite time. Such portions as are necessary to care for the sewage of Rockaway and Far Rockaway should be provided at an early date.

Summary.

Following is a summary of the more important data concerning the proposed sewerage of the Jamaica Bay division.

	Barren Island.	Jo Cos Marsh.	Total.
Area drained, acres.....	35,739	17,920	53,659
Population served	1,192,400*	223,300**	1,415,700
Mean volume of sewage—million gallons daily..	166	38	204
Cost of works.....	$11,830,000	$2,383,000	$14,213,000
Annual charges including interest at 4½% and sinking fund for 50 years	$964,643	$239,980	$1,204,623



*Estimated for year 1960.

Report on the Estimate of the Central Committee that the Dry Weather Sewage Flow in the Metropolitan Sewerage District is Not Less than 125 Gals. Per Head Per Day.

February 6th, 1912.

John W. Alvord and Chas. B. Burdick, Hydraulic and Sanitary Engineers, Hartford Building Chicago.

1 *Report on the Estimate of the Central Committee that the Dry Weather Sewage Flow in the Metropolitan Sewerage District is Not Less than 125 Gals. Per Head Per Day.*

Volume of Sewage of Communities in the Metropolitan Sewerage District.

"Very few data concerning the actual discharge of sewage from the above named communities are available. Generally the water consumption is taken as the measure of the dry weather flow of sewage, but it must be remembered that appreciable quantities of water derived from independent sources of supply are used in most cities for industrial purposes, and that the sewers also receive a considerable amount of ground water by infiltration. In view of the fact that most of the larger communities in the District contain many industries, the central committee is of the opinion that a conservative estimate of dry weather flow of sewage is 125 gallons per head per day, on the average for the entire district, both at the present time and in the future. In arriving at this figure, it was assumed that measures would gradually be taken by most of the communities to check undue waste of water."

To satisfy myself that this estimate is conservative, I have made a careful study of the data which is available, and herein briefly review the conclusions which result from these studies, as follows:

As pointed out by the Central Committee, the water consumption is taken as a measure of the dry weather sewage flow, but that
2 this is considerably augmented by industrial waste, the water being supplied from independent sources, as well as infiltration of ground water into the sewer.

Water Consumption is an Index to Sewage Flow.

In the absence of continuous gaugings covering long periods of time, on sewered areas of known population, it becomes necessary to derive an estimate of the dry weather sewage flow by some other measure. It has often been the practice among engineers engaged in this line of work, to assume the per capita dry weather sewage flow equal to the per capita water consumption. This does not mean that

all the water supply is delivered to the sewer. There are a number of ways in which water may be used in such a way that it does not find its way to the sewer, among which are such uses of water as by steam railroads, some manufacturing and mechanical purposes, street and lawn sprinkling, etc.

At Milwaukee the Sewerage Commission in 1910 estimated the water which did not reach the sewer, as follows:

	Gallons per capita per day not reaching the sewer.
Steam railroads	5
Manufacturing and mechanical	5
Street sprinkling	5
Lawn sprinkling	2½
Consumers not connected to sewer	7½
Leakage from water mains & services	15
Total	40

3 This total of 40 gallons per capita represents about 38% of the total water supply. Probably considerable of the leakage from the mains and services finds its way to the sewer as ground water. The Commission assumed in making an estimate of the dry weather sewage flow that 35% of the water supply failed to reach the sewer.

Inasmuch as the water consumption is the principal factor determining the volume of the domestic sewage, I have prepared the following Table No. 1, giving the population and per capita water consumption of a number of cities. This table also gives the percentage of services that are metered, as this undoubtedly greatly influences the per capita consumption.

Table No. 2 gives the population of the various communities in the Metropolitan Sewerage District with the average water consumption at the present time in gallons per head per day for such communities where these data are available. The populations are as given in the 1910 U. S. Census.

From table No. 1 we find that in the seventy cities enumerated, the average consumption per capita daily to be 148 gallons. This average is determined by giving each city its relative weight in proportion to its population. This is done because in general the larger the city the larger the per capita consumption, and it is evi-

4 dent that the conditions in the larger cities are more nearly comparable with those in the Metropolitan District.

Considering Table No. 2, which is quite incomplete on account of the fact that the data pertaining to the water consumption in the various communities within the Metropolitan area is not available at this time, is probably the best index as to the average sewage flow to be expected from this area. From this table it appears that for the City of New York the average daily consumption of water per capita is 114 gallons. For the cities exclusive of the City of New

York, the average water consumption per capita is 111 gallons for the communities listed in Table No. 2, where the consumption is known. The total population of the communities in which the per capita water consumption is available, amounts to 5,998,342, of which, 4,937,243 reside in the City of New York. These data are therefore available for approximately 93.5% of the total population of the Metropolitan District which is 6,424,530, according to the U. S. Census for 1910.

Infiltration of Ground Water.

It is known that in a sewerage system, either sanitary or combined, the sewage flow is made up partially of ground water. This being caused by the ground water adjacent to the sewers, being at a higher level than the sewer, causing a seepage of this water through the joints into the sewer. The amount of this leakage into the sewer is most largely dependent on the pervious or impervious character of the soil. Aside from this factor, the elevation of the ground water level with reference to the sewer, and the perviousness of the sewer itself, are of importance. It is possible to somewhat reduce the amount of ground water leakage by care in construction, but from an economical standpoint, it is usually undesirable to build sewers so that the infiltration of ground water is completely prevented, as in most cases the lowering of the ground water is a valuable and important function of the sewer.

Actual measurements of the ground water flow are too meager to be of general value, and it is evident in any event, that it would be impracticable to determine the part of ground water in the sewers of the Metropolitan area by actual gaugings. It has been suggested that minimum flow during the night is practically equal to the ground water infiltration. This is probably very nearly the case in residential districts, although even here the flow caused by leakage from house fixtures, etc., would vitiate the above assumption. In districts containing industries using water throughout the twenty-four hours, no dependance could be placed on this method of obtaining measurement of the ground water leakage.

The amount of ground water entering the sewer is obviously independent of the population, and is usually expressed in gallons per acre per day, or gallons per mile of sewer per day. Expressing this flow in reference to miles of sewer is undoubtedly better than in reference to acreage, as the amount of seepage is undoubtedly proportional to the length of sewer laid, assuming that the local influencing condition is the same. To facilitate estimating the total flow in sewer districts, the unit gallons per head per day is usually used and for this reason it becomes necessary to express the ground water infiltration in this unit. It is possible to do this after the leakage per mile of sewer and the population on the area drained has been determined.

The Milwaukee Sewerage Commission recently had continuous gaugings covering a period of several days, made of a 72" sewer draining 358 acres of strictly residential portion of that city. Assuming the ground water infiltration equal to the minimum night

flow, it was found equivalent to 36,000 gallons per mile of sewer, 956 gallons per acre, or 31 gallons per capita. This sewer district is on comparatively high ground and the soil is of such a nature that the ground water infiltration is considerably less than in some of the lower portions of the city. The Commission came to the conclusion that the average leakage was 38 gallons per capita and the maximum rate was 76 gallons per capita.

7 From a study made of the data collected by the Engineers of the Metropolitan Sewerage Commission, Boston, relating to the flow in the North Metropolitan intercepting sewer, it is deduced that the ground water infiltration is equivalent to from 38.3 to 61.6 gallons per capita daily.

The following is a table showing the allowance made for ground water infiltration in various cities by engineers who have studied this matter.

Allowance Made for Ground-water Infiltration in Various Cities.

	Gals. per capita per day.			Gals. per acre per day.		
	Min.	Ave.	Max.	Min.	Ave.	Max.
Paterson, N. J. (Report of Joint Com. Sewage Disposal, '06, pp. 111)		14				
Louisville, H. P. Eddy		58				
Passaic Valley (Report Passaic Valley Sew. Com., 1908, p. 7)			29			
Milwaukee (Report Sewage Com., 1911)		38	76			
Neponset Intercepter, Boston (Report Met. Sew. Com., 1895, p. 38)			25			
High Level Sewer, Boston (Report Met. Sew. Com., 1899, p. 44)			24			
San Francisco (Grunsky's Report)	32*		97*	640		1,940
Indianapolis (Hering's Report, 1892)		25*			500	

* Computed from gals. per acre, assuming 20 people per acre.

8 From the table, and the observations cited hereinbefore, it is safe to assume that the ground water infiltration in a sewered area such as the Metropolitan Sewerage district, would average at least 25 gallons per capita per day.

Industrial Wastes.

No effort has been made to obtain complete information as to the quantity of industrial wastes discharged into sewers in the Metropolitan Sewerage District by industries obtaining their water from private sources. The only way to accurately determine the volume of industrial wastes in the Metropolitan area would be by a complete census of all the varied industries located within the district. This is probably at this time impracticable, and we must therefore, be satisfied with an estimate based on such data as *is* available.

In studying the question of industrial waste at Milwaukee, the Sewerage Commission adopted the allowance of 57 gallons per capita to cover a portion of the flow,—this amounting to 34.6% of the total sewage flow of 165 gallons per capita daily.

Sewage Flow Per Capita in Various Cities.

Records of gaugings of the dry weather flow in sewers are quite limited, especially gauges covering long periods of time. In table No. 3 I have tabulated such information on this subject which I have collected from various sources. Possibly the best records of sewer gaugings covering a long period of time, are those made by the Metropolitan Sewerage Commission at Boston. These records are fully discussed in the appendix No. 1 attached hereto, taken from the report made by the Milwaukee Sewerage Commission in 1911. It would be of no significance to average the various quantities in this table as some of these are simply single guagings, while others covered periods of various lengths, including several estimates recommended to be used in several cities by engineers after making a study of this question.

It will be seen from the table that there is a great variation in the flow to be expected, and that this variation is considerably greater than the variation in the water consumption in various communities as shown in Table No. 2, which would tend to show that in determining the average sewage flow, other sources of sewage besides the public water consumption must be taken into consideration.

Report of Metropolitan Sewerage Commission of New York.

The Metropolitan Sewerage Commission of New York in their report of 1910 commented on the volume of sewage discharged into New York Harbor, as follows:

"The volume of sewage produced in any district depends primarily on the water consumption, including that obtained from wells or other private supplies. In some towns, such as Paterson, these private supplies furnishing artesian water for manufacturing purposes, such as dye works, silk mills, rolling mills, breweries, etc., constitute an important proportion of the total amount of water used. If discharged into the sewers as is customary, it adds to the volume of the sewage, although it may not increase the total amount of the organic constituents of the sewage.

Aside from the water supply the flow of sewage may be materially increased by the infiltration of ground water through leaky sewers, or of surface waters through manhole covers. In the case of combined sewer the flow is enormously increased for short periods during storms.

On the other hand the volume of sewage carried by the sewers is diminshed, first, by the fact that suburban or rural areas are not provided with sewers, their liquid wastes going either to cesspools or on to the land; second, because in many instances manufacturing wastes are discharged directly to the nearest streams without passing through a sewer; third, by leakage from defective sewers into the soil, and fourth, on account of water used for street sprinkling and street cleaning purposes.

In a combination of towns such as is represented by those of the metropolitan district, it is believed a fair general estimate of the volume of sewage may be determined with the following assumptions:

1st. That the infiltration of surface and ground water to some sewers and the water used from private supplies will about offset that lost by leakage or by the ordinary direct disposal of streams and by street sprinkling.

2nd. That where an unusual discharge directly to streams is made from the mills, etc., due allowance to be made for this.

3rd. That the run-off directly due to storms be disregarded by assuming the dry-weather flow only of combined sewers.

4th. That districts without sewage facilities be omitted from consideration.

From these assumptions it follows that for the general purposes of this estimate the volume of sewage may be taken as equivalent to the water supply, corrected for any excessive discharge from other sources, or diversion to other outlets, by mills, etc.

11 In this way fluctuations due to non-resident population are accounted for without determining the number of people, the water supply being known."

Applying this method to the metropolitan district, this Commission prepared Table No. 4, setting forth the estimated sewage flow in 1910 and 1940. These estimates were made before U. S. Census — for 1910 were available and are therefore now subject to some correction, especially the forecast for 1940. Assuming the estimates for 1910 to be substantially correct, the total sewage flow for the Metropolitan district in 1910 amounts to 802 million gallons daily. The total population in 1910 according to the returns of the U. S. Census is 6,424,530, which amounts to a sewage flow of 125 gallons per head daily.

Conclusions.

That the estimate of an average sewage flow of 125 gallons per head per day for the Metropolitan district made by the Central Committee, both for the present time and in the future, is conservative, seems to be shown by practically all the data which I have collected on this subject. The estimate of the Metropolitan Sewerage Commission of New York shows present quantity amounting to 125 gallons per head daily and increasing considerably in the future.

12 The data relating to the water consumption amounting to 113 gallons per capita for 93.5% of the total population of the Metropolitan area would indicate that this will not be materially altered by the per capita consumption in the balance of the district. Assuming that 113 gallons represents the correct per capita water consumption daily and that due to reasons hereinbefore given, but 80% of this water actually reaches the sewers. This would amount to practically 90 gallons per capita. To this we must add an allowance for ground water infiltration which could be conservatively estimated at 25 gallons per capita. This would leave but 10 gallons per capita unaccounted for to take care of industrial waste, etc., the water being drawn from private sources.

The estimate of the Central Committee of 125 gallons of sewage per head per day is therefore conservative, and in my opinion, it is too low rather than too high.

13

22 APPENDIX No. 1.

Extracts from Report of the Milwaukee Sewage Commission on the Quantity of Sewage Likely to be Produced.

April 25th, 1911.

By John W. Alvord, Geo. C. Whipple, Harrison P. Eddy, Commission.

23 Recommendation of Commission as to Quantity of Sewage to be Provided for: The average volume of sewage at the present time is estimated to be 61,000,000 gallons per day. Guided by the estimated future population and area, and a study of the water consumption and its probable increase, the amount of water likely to be used for manufacturing, and the amount of ground water leaking into the sewers, we have estimated that in 1930 the average daily volume of sewage for a considerable period of time each year, will be about 100,000,000 gallons, and in 1950, 155,000,000 gallons. The maximum rate of flow of sewage is now estimated to be about 107 million gallons daily, in 1930, 176 million gallons, and 265,000,000 gallons in 1950. The latter is equal 312 gallons per capita.

Data upon which Above Recommendation Was Made.

Actual Quantity of Water Supply Reaching Sewers.

As shown in detail in the consideration of the flow of sewage in the North Metropolitan intercepter in Boston, the quantity of sewage flowing in dry weather is frequently equivalent to not over ninety per cent of the water consumption. It cannot be reasoned from this fact however, that ninety per cent of the water supply is delivered to the sewer.

There are many ways in which water is used or lost without 24 finding its way to the sewers. Among these may be mentioned railroad uses, water used for steam purposes, street and lawn sprinkling, that supplied to buildings not connected with sewers, and, probably the largest item of all, leakage from the water mains and services. The losses from these sources may be estimated as follows, based upon an assumed supply in Milwaukee in 1910 of 105 gallons per capita per day:

TABLE 18.

Estimated Quantities of Water Furnished by Water Works which do Not Reach the Sewers.

Milwaukee, 1910.

	Gals. per capita per day.
Steam railroads	5
Manufacturing and Mechanical purposes	5
Street Sprinkling	5
Lawn Sprinkling	2½
Consumers not connected with sewers	7½
Leakage from mains and services	15
Total	40

The total of these losses (40 gallons per capita per day) is equivalent to slightly over 38% of the supply. This estimate is based upon fragmentary and, in some cases, unsatisfactory information, but it seems reasonable to assume that at least 35% of the water supply will fail to reach the sewers by way of the house drains.

It should be mentioned in passing, that the leakage from the water mains and services tends to increase the supply of ground water, and that doubtless much of this water may eventually find its way into the sewers in the form of leakage.

25 The quantity of the municipal water supply estimated to reach the sewers, is therefore in round numbers as follows:

TABLE 19.

Estimated Quantity of Municipal Water Supply which Will Reach the Sewers.

1910	70	gals.	per	capita	per day.
1920	72½	"	"	"	"
1930	75	"	"	"	"
1940	80	"	"	"	"
1950	85	"	"	"	"

Ground Water.

As indicated by the name, this classification includes such waters as find their way by means of leakage from the ground into the sewers. It is also intended to include such surface water as leaks through perforated manhole covers and defective brickwork in manholes, and the surface water which flows during comparatively dry weather and after the run-off ordinarily considered as storm water has ceased to flow, in small natural brooks necessarily connected with a sewer system built upon the combined plan.

While a large proportion,—probably in Milwaukee from 50 to 75

per cent.—of the rainfall runs off into the sewers very quickly after it has fallen, and is therefore properly called storm water, the remainder slowly percolates into the ground and supplies the natural underground streams, and is here referred to as ground water.

Sewers are often necessarily built at such a depth as to lie
26 below the natural surface of such waters, and if they are not perfectly tight,—condition almost impossible to obtain,—there is more or less leakage into the pipes, with a consequent lowering of the ground water level.

Another source of ground water is the filtration from the rivers into the land lying near them. It is quite possible, in a city located like Milwaukee, that more or less of such water will find its way into the sewers lying comparatively near to the rivers.

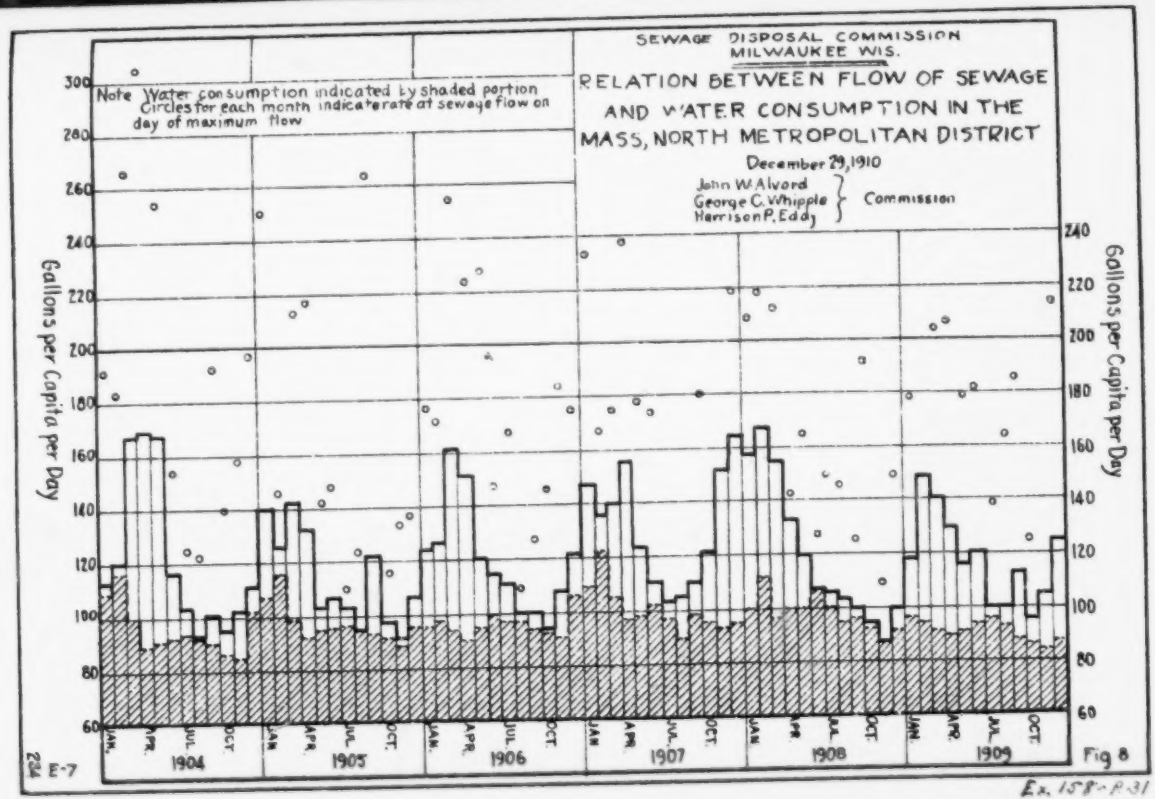
The natural ground water (not the water filtering from the rivers) varies in elevation from season to season. During the spring when the frost is coming out of the ground and leaving the soil porous, so that the rain and melting snow can penetrate it easily, the supply of ground water is greatly increased, and the elevation of the water table usually rises several feet. As this water flows away through natural channels, or finds its way by infiltration into the sewer system, the elevation of the ground water is gradually reduced, and as this reduction takes place, there is less head upon the sewers and the quantity of infiltration becomes gradually less and less, until if the supply is not replenished, the quantity of leakage from this source may be reduced to nil. It is also true that the elevation of ground water varies from year to year with the quantity and distribution of rainfall.

27 The sewers first built in a district usually follow in a general way the natural water courses, and therefore lie in the bottoms of the valleys. Such sewers are often, especially in case of combined systems, built very close to, or actually in the natural beds of brooks. They are not usually extended to the extreme upper end of the district at first, and consequently the natural run-off through these brooks is taken into the sewers. Such brooks frequently flow, with gradually diminishing volume, for many days after the immediate run-off from a storm has passed by, and perhaps even throughout the dry season. The flow during the remainder of the time, until the next storm, is made up of the water draining out of the land, and is therefore logically classed with ground water, and, as its flow is continuous though gradually diminishing, it has the same effect upon the quantity of sewage. As a result of these conditions, such sewers receive comparatively large quantities of ground water, while it is but natural to expect that sewers built in these districts in later years, necessarily at higher elevations, will receive smaller quantities of leakage and brook flow.

Many measurements have been made to determine the quantity of ground water which finds its way into sewer systems. The results of these observations, indicate that the quantity of infiltration may be as low, under the most favorable conditions, as 5,000 or
28 10,000 gallons per day per mile of sewer. On the other hand, they show that the leakage frequently amounts to from 20,000

to 40,000 gallons per day, and at times of very high ground water, or during rain when there is leakage through manhole covers, even in separate systems it may run as high as 100,000 gallons per day per mile of sewer. In fact, there are instances where the leakage has materially exceeded this quantity.

As a rule, there has been a growing tendency toward securing as nearly water-tight construction as possible, so that it is undoubtedly true that the older systems receive greater quantities of ground water than some of the better constructed modern systems.



A Study of Records of Quantity of Sewage Delivered by the North Metropolitan Sewer, Boston, Mass.

Obviously, it has been impossible for us to obtain complete data regar-ing the quantity of sewage produced at Milwaukee, with observations of the rate of flow at different hours of the day, days of the week and seasons of the year. Such information can be collected only by continuous records extending over several years, and it is practicable to collect it only when the sewage is delivered to a single point instead of being discharged at many different points, as at Milwaukee. For this reason it has been deemed wise to make a study of such records collected in other places, and to apply
29 the lessons drawn from them to conditions at Milwaukee, giving proper weight to differences in local conditions.

The best data relating to the flow of sewage, available for study, appear to be those collected by the Engineers of the Metropolitan Sewerage Commission, Boston, Mass., who have practically continuous records extending back over many years. Our study has been confined, for the most part, to data relating to the North Metropolitan intercepting sewer. The district served includes 15 cities and towns, many of which are provided with the separate system of sewers. The cities of Cambridge, Everett, Chelsea and Somerville, and the Charlestown and East Boston districts in the City of Boston, which are served by this intercepter, are sewered upon the combined plan, and automatic regulators are provided at the sewer intersections, so that when the intercepting sewer is full, the gates are partially or wholly closed, and the surplus flow in the trunk sewers is discharged directly into the water courses or the harbor.

This sewer was designed to serve a territory of 46,000 acres, and a population of 571,000 in 1930. In 1909, the area served was 18,560 acres and the population 511,500.

Table 20 is a compilation of certain data based upon the entire population of the district tributary to this sewer, for the years 1904 to 1909 inclusive. The average quantities of sewage per day, per acre and per capita, (columns 3 and 4) are doubtless some-
30 what greater than if the storm water from the districts sewered on the combined plan was not received; but as those quantities represent the monthly averages, the error is probably not serious. On the other hand, there are overflows from the intercepter, which reli-ve it at times of excessive flow. Column 5 purports to be the maximum quantity per capita for a single day, but is obviously

considerably lower than the actual quantity, if the sewer were ample to provide for the district as originally planned. On account of the tributary combined systems, these quantities are all more or less affected by storm water, although it is apparent that but little can be accommodated.

The yearly averages of the quantity of sewage and of the water consumption are given in Table 21, which also shows the relation between the average quantity of sewage and the average water consumption. Column 5 is made up of the percentage which the quantity of sewage is of the water consumption. It will be noted that this percentage varies from 115.7 to 128.7. It would seem to be a reasonably fair assumption for this district that the sewage flow would on an average be about 25% in excess of the quantity of water consumed.

(Here follows diagram, Fig. 8, marked page 31, Complainants' Exhibit 158.)

Fig. 8 shows graphically the relation between the average quantity of sewage and water consumption, as well as the maximum quantity of sewage for a single day. The shaded portion shows the quantity of water consumed. The shaded portion plus the unshaded portion below the heavy line, represents the quantity of sewage. The
32 small circles show the maximum quantity of sewage for a single day in each month.

TABLE 21.

Relation of Quantity of Sewage to Water Consumption, North Metropolitan Sewer District, Boston, Mass.

(Based on total population of district.)

Year.	Precipitation, inches.	Avg. sewage flow, gals. per capita.	Avg. water consumption, gals. per cap.	Ratio sewage to water, %.
(1)	(2)	(3)	(4)	(5)
1904	42.82	121.5	96.0	126.6
1905	42.31	113.5	98.1	115.7
1906	44.48	119.4	97.4	122.6
1907	44.38	129.6	102.7	126.2
1908	36.15	119.0	99.2	120.0
1909	41.75	118.4	92.0	128.7
Average				123.3%

34 Similar data, based upon the number of people actually connected with the sewer system, Table 22, show a ratio of sewage flow to water consumption much higher than where the entire population is used as the basis of calculation. This ratio varies from 140 to 162%. In considering these figures, however, it should be borne in mind that those buildings and industries most needing sewers, and therefore first accom-odated, are usually the ones having the greatest quantity of wastes to dispose of. The outlying and scattered population, which is not supplied with sewage facilities, would probably not use as large a quantity of water, or have as large a quantity of sewage to be disposed of, as the denser population and the manufacturing and mercantile districts.

TABLE 22.

Relation of Quantity of Sewage to Water Consumption, North Metropolitan Sewer District, Boston, Mass.

(Based on number of persons connected with sewer system.)

1904	156	96.0	162.5
1905	145	98.1	147.9
1906	151	97.4	155.0
1907	152	102.7	148.0
1908	139	99.2	140.1
1909	136	92.0	147.8

It is interesting to note that in spite of the fact that large tributary areas are provided with combined sewers the average
35 quantity of sewage seems to bear little or no relation to the average rainfall. This may be due in part to the small size of the intercepter, which has little capacity in excess of the requirements for fair weather and can therefore, carry only a very small quantity of storm water.

While the actual measurements of sewage are usually in excess of the measurements of water furnished to the same population, it should not be assumed that all of the water supplied to the community is delivered to the sewers. In fact, there are several days in the course of the year when the average sewage flow is actually less than the water supply. In January, 1904, August, 1905, August and September, 1906, August and July, 1907, and November, 1908, the average flow of sewage for the entire month was less than the average quantity of water supplied to the tributary population.

The sewage of a community is made up not only of the water received from the water supply, but also of ground water leaking into the sewers, storm water leaking through manhole covers, industrial and mercantile wastes, (the supply for which is obtained from sources other than the municipal supply), and storm water, where the sewers are built to receive storm water as well as sewage. It not infrequently happens in districts provided with separate sewers, that connections are made, with or without authority, through which roof water, and sometimes the drainage of areas is admitted.

An effort has been made to estimate the average quantity
36 of sewage flowing in the North Metropolitan Intercepter, exclusive of storm water, for certain months during which the rainfall was low, and in which the ground water also might be expected to be low. To aid in these studies, Fig. 9 has been prepared. The solid line represents the actual recorded quantity of sewage pumped, while the dotted lines indicate the estimated quantity of sewage excluding the storm water. By eliminating the quantities above the dotted lines, an approximation has been made of the average flow of sewage, exclusive of the run-off from storms. In the case of September, 1906, this quantity amounted to 44.8 million gallons per day. The water consumption for the same period of time was 48.8 million gallons per day. The quantity of sewage was therefore 91.9% of the quantity of water supplied to the community. Similar computations were made for six other dry months, with the results given in Table 23.

38 In all cases, the quantity of sewage doubtless includes some ground water, and the usual quantity of manufacturing wastes, the water for which is derived from sources other than the water supply.

As has been pointed out, ground water stands or flows at a higher elevation in the spring than during other seasons of the year. A study of the records of the North Metropolitan sewer for the month of April in several years throws some light upon the average quantity of leakage which may be expected during that month. In a manner similar to that already described in determining the ratio of dry weather flow of sewage to the water consumption, Fig. 10 has been plotted, showing by the solid lines, the sewage pumped for each day of the month. The dotted lines indicate the probable quantity of sewage eliminating the storm water. Taking April, 1906, as an illustration, it appears that the quantity of sewage averaged 70.2 million gallons per day. Ninety per cent of the water consumption, which has been found to be equivalent to the dry weather flow in the intercepter, was 40.2 million gallons daily, leaving a surplus at this time of 30 million gallons per day. As the quantity of manufacturing wastes for the district were included in figures upon which the estimate of the dry weather flow of sewage (90% of water consumption) was based, it is evident that this difference of 30,000,000 gallons per day represents the quantity of ground water in excess of that present in very dry weather, which found its way by

39 infiltration into the sewers. As there were 652.5 miles of sewers tributary to the system at that time, the excess leakage averaged 46,000 gallons per day per mile of sewers. The tributary area was 17,561 acres, making the average daily leakage, (in excess of that during very dry weather), say 1,707 gallons, while the daily leakage per capita was 61.6 gallons.

(Here follows diagram, Fig. 10, marked page 40, Complainants' Exhibit 158.)

The month of April in four different years has been studied in a similar manner, and the results are given in Table 24.

TABLE 24.

Estimated Average Daily Quantity of Ground Water Leaking into North Metropolitan Sewer System in April, Boston, Mass.*

	Leakage, gals. per mile of sewers.	Leakage, gals. per acre.	Leakage, gals. per cap.	Rainfall.	
				Inches.	Previous month.
(1)	(2)	(3)	(4)	(5)	(6)
April, 1904.....	47,900	1,727	62.7	9.28	2.84
April, 1905.....	33,700	1,240	44.5	2.63	2.86
April, 1906.....	46,000	1,707	61.6	2.32	7.32
April, 1909.....	27,600	1,056	38.3	3.92	3.90

From this table, it appears that the average quantity of leakage in April in excess of that in August, varied from 27,600 to 47,900 gallons per day per mile of sewer, and from 1,056 to 1,727 gallons per day per acre. The largest quantity of leakage was in April, 1904, when the rainfall for the month was 9.28 inches. The next largest quantity was in April, 1906, when the rainfall was but 2.32 inches; but during the previous month there was a rainfall of 7.32 inches, which undoubtedly had much to do with the high ground water of the month in question.

41 To these quantities should be added the leakage during the dry weather, when the sewage was found to be equivalent to 90% of the water consumption. It is extremely doubtful if this leakage ever falls below 10,000 gallons per day per mile of sewers. Adding 13,000 gallons per mile to the quantities given in Table 24, the total average leakage per acre and per capita per day would be as shown in Table 25.

* In excess of ground water leakage during month of August.

TABLE 25.

Estimated Average Daily Quantity of Ground Water Leaking into North Metropolitan Sewer System.

(Assuming that leakage during driest months = 10,000 gals. per day per mile of sewer.)

Month.	Leakage in gallons per day per		
	Mile of sewer.	Acre.	Capita.
(1)	(2)	(3)	(4)
April, 1904	57,900	2,089	76
" 1905	43,700	1,607	58
" 1906	56,000	2,078	75
" 1909	37,600	1,469	52

In considering these figures, it must be remembered that they are average figures for the entire month, and it can readily be seen that the maximum quantity of leakage would be far in excess of this quantity. On the other hand, the tributary area is very completely sewered—23.8 miles of sewers per square mile—and many of the trunk sewers lie in wet ground and were built at a time when less care was taken to exclude ground water than at present. In calculating this area, only the districts directly tributary to sewers now built are included, and as they are located within a much larger tributary but unsewered area, the unit leakage is undoubtedly higher than will be the case when the entire district is completely sewered.

42 Miles of Sewers Per Unit of Area.

Table 26 compiled from data furnished in the special report of the United States Census Bureau upon "Statistics of Cities for 1905," shows the number of miles of sewers existing in various cities of the United States at that time. It appears that Boston had the greatest mileage,—18.4 miles of sewers per square mile of area,—while Milwaukee was second with 17.2 miles. These figures undoubtedly include areas somewhat suburban in nature which were not completely sewered. It would seem therefore, that an estimate of about 17 miles of sewers per square mile would be reasonable for Milwaukee in the future.

Estimate of Ground Water Reaching Sewers in Milwaukee.

There are certain portions of Milwaukee which yield considerable ground water, and others in which the soil is of blue clay and hardpan where scarcely any water is met in excavations for sewers. Comparatively small areas are low and lie adjacent to the rivers, but as a rule the land rises rapidly from the rivers. There are no indications of unusual leakage here, and provision for leakage amounting at times to 70,000 gallons per mile of sewer would appear to be ample.

We have assumed an allowance of 1,960 gallons per day per acre for maximum leakage. If the extent of the sewers is taken as 17 miles per square mile, this allowance for ground water corresponds to a leakage of 73,700 gallons per mile of sewers. So great a
43 quantity of leakage will be of comparatively short duration, but the studies of the records of the North Metropolitan System, and experience in other places indicates that at least as much as one-half this quantity or 980 gallons per day, per acre may be expected for a month or more at a time. These allowances may be summarized as follows:

Maximum Rate of Leakage.

1960 gals. per day per acre, or approximately 0.003 cu. ft. per second per acre.

Rate of Leakage Probable for One or Two Months at a Time.

980 gals. per acre per day, or approximately 0.0015 cu. ft. per second per acre.

Quantity of Leakage at Maximum Rate, 1910.

(1960 x 14,374) = 76 gals. per day per capita.

373,857

Quantity of Leakage Probable for One or Two Months at a Time.

38 gallons per capita.

44

45 Discussion of Results of Measurements of the Flow of Sewage from District No. 47, Milwaukee.

This district, comprising 358 acres, is residential in character and no industrial or mercantile wastes are known to be discharged into the sewer. It is completely sewered and practically built up, the density of population being 30.7 persons per acre, corresponding to a total population of 11,000.

The gaugings, covering a period of four days, were made in the 72 inch sewer in 15th Street, near the northerly line of Grand Avenue. The district tributary to this sewer lies between the northerly line of Grand Avenue and the southerly line of Walnut Street, and, in a general way, between 14th and 23rd Streets.

The results of these sewer gaugings have been summarized as follows.

TABLE 28.

Sewer Gaugings.

	Total quantity.	
Monday (8 A. M. Oct. 24 to 8 A. M. October 25)	950,000 gals.	
Tuesday (8 A. M. Oct. 25 to 8 A. M. October 26)	911,000 "	
Wednesday (8 A. M. Oct. 26 to 8 A. M. October 27)	884,000 "	
Thursday (8 A. M. Oct. 27 to 8 A. M. Oct. 28)	931,000 "	per day
Average	919,000 "	" "

Using these quantities as a basis of calculation it appears that the average flow of sewage per capita was as follows:

46 TABLE 29.

Sewage Flow Per Capita Per Day.

(30.7 persons per acre.)

Monday	86.4 gals.
Tuesday	82.8 "
Wednesday	80.4 "
Thursday	84.6 "
Average	83.5 "

The average quantity of sewage found to be flowing in this sewer was 83.5 gallons per capita per day. This consists of ground water and that portion of the water supply discharged into the sewers.

It has some times been suggested that an indication of the quantity of ground water flowing in sewers can be obtained by assuming that the minimum rate of flow during the night is equivalent to the ground water infiltration. Obviously the quantity of ground water finding its way into the sewers is the same at night as during the day, and it is also true in many cases that the quantity of sewage actually contributed to the sewers during certain hours of the night is extremely small, if not nil. As this is a residential district, it is probable that no serious error will result from the assumption that in this case the minimum rate of flow during the night represents the quantity of ground water leaking into the sewer system. The minimum rate of flow on each of the days when gaugings were made, reduced to gallons per capita, was found to be as follows:

TABLE 30.

Minimum Rate of Flow.

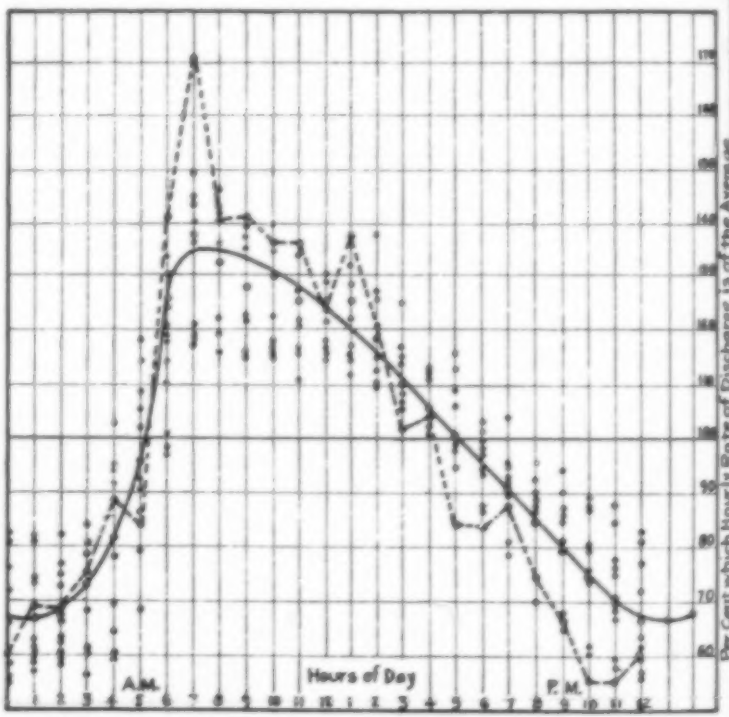
Tuesday (12:30 A. M.)	31.1	gals. per Cap. per day.
Tuesday (11:00 P. M.)	40.5	" " " " "
Thursday (1:00 A. M.)	38.2	" " " " "
Friday (1:00 A. M.)	39.1	" " " " "
Average	37.2	

The rate of flow was smallest at 12:30 A. M. Tuesday when the quantity of water flowing in the sewer was equivalent to 956 gallons per acre per day, corresponding to 31 gallons per capita per day. If it is assumed that this quantity represents the ground water, the remainder of the flow would represent the water supply reaching the sewer, amounting to 52.5 gallons per capita per day.

The fluctuation in the maximum rate of flow was very marked, being from 133 to 207 gallons per capita per day. The maximum rate of flow on each of the days when gaugings were made, was found to be as follows:

TABLE 31.

Maximum Rate of Flow.



Monday (10:30 A. M.)	207	gals. per cap. per day.
Tuesday (10:30 A. M.)	133	" " " " "
Wednesday (8:00 A. M.)	149	" " " " "
Thursday (8:00 A. M.)	168	" " " " "
Average	164	gals. per cap. per day.

The ratio of the average maximum rate of flow to the average daily rate of flow $\frac{(164)}{(83.5)}$ is 1.96; that is, the average maximum rate

of flow was found to be nearly double the average daily flow.
48 This average maximum rate, however, is obtained by averaging the maximum rates of flow found on all of the four days when measurements were taken. These maximum rates, however, did not occur at the same hour of the day in each case, so that somewhat different results would be obtained by averaging the rates of flow for the same hour and selecting the maximum from this set of averages. The broken line, Fig. 11, shows the average rate of flow for each hour from District 47, for the four days covered by these gaugings.

This district is comparatively small in area, and the sewers are short and have rather steep grades. The longest sewer is about 1½ miles in length, and most of them are considerably shorter. The district is approximately rectangular in shape, about 5,000 feet long and 3,000 feet wide, on the average. On account of the size, shape, topography and residential character of the district, the measurements of the sewage show a fluctuation corresponding closely with that which would be expected. The fluctuation in the flow from the entire city at the outlet of the intercepting sewer will be very different from that of this or any other district, because of the equalizing effect due to difference in the length of trunk sewers in different districts, difference in the character of the districts, and storage in the intercepting sewers; so that the maximum rate of flow in and from the intercepting sewers will not be the same as that in the trunk Sewer of District No. 47.

Fig. 12.

The relative hourly rates of flow as obtained by measurements taken in various cities, are indicated by the dots upon Fig. 11. The results of averaging these measurements are indicated on the diagram by the small circles. The solid line is a curve drawn through many of the average points, and presents fairly well the average hourly fluctuation in the flow of sewage. In preparing this diagram, allowance has been made for the time consumed by the sewage in flowing to the gauging stations, and the gaugings have been so arranged that the early morning rise in flow shall come at substantially the same time in all of the cities. From this diagram it appears that the maximum rate of flow is, under average conditions, about 1.35 times the mean flow.

In Fig. 12 curves have been plotted showing the hourly fluctuation in the rate of flow in the North and South Metropolitan intercepting sewers, Boston. From these curves it appears that the maximum rate of flow in the North intercepter is only about 1.18 times, and in the South intercepter 1.09 times the average rate. In considering these curves it should be remembered that the intercepting sewers are very long and receive the sewage of many different cities and towns, which fact doubtless accounts for the smaller variation in flow than is shown by the curve in Fig. 11. It seems probable also that the fluctuation in the rate of flow from the City of Milwaukee would be somewhat greater than that of the North Metropolitan District.

(Here follows diagram, Fig. 12, marked page 51, Complainants' Exhibit 158.)

The average rate of flow through the day time, say from 9 A. M. to 5 P. M. in District 47, for the four days when the flow was gauged, was 1.33 times the average rate of flow for 24 hours.

52 Industrial Wastes.

Milwaukee is essentially a manufacturing city, being fortunate in the possession of many and varied industries. Several of these produce comparatively large quantities of waste liquors which are now discharged into the sewers or rivers. No effort has been made to obtain a complete census of the quantity of industrial wastes, although several of the manufacturies known to produce large quantities of waste liquors was visited, samples of the wastes collected for analysis and estimates made of the quantity of water used, as an index to the quantity of wastes which will be likely to be discharged into the sewers. The results of this investigation, so far as they pertain to the quantity of wastes are given in Table 32.

TABLE 32.

Quantities of Water Used by Several Manufacturies in Milwaukee.

Plant. (1)	From private water supply. (2)	City water. (3)
	(Gals. per day.)	
Plankington Packing Co.	400,000	.....
Layton Packing Co.	200,000	Boilers only
Bodden " "	45,000	55,000 gals.
Gunz " "	80,000	per day
Pabst Brewery	1,000,000 to 2,000,000	.....
Schlitz "	2,000,000	1,000,000
Blatz "	500,000	400,000
Pfister & Vogel's Tannery	800,000	400,000
Trostel & Sons	600,000	.....
American Hide & Leather Co.	350,000	.....
Milwaukee Coke & Gas Co.	475,000	.....
Total	7,450,000	gals. per day.
Johns-Manville Asbestos Works		500,000 (not now within city limits).

53 This quantity of water taken from private supplies is equivalent to about 20 gallons per capita per day. There are no doubt many other industrial plants provided with water from private sources, so that the total of such supplies will materially exceed this quantity; in fact, a consumption of 50 or 60 gallons per capita per day from private sources, is not unreasonable. The greater part of this water is likely in the future to be discharged into the sewers after it has been used, although this may not be true at the present time.

Additional light is thrown upon the quantity of industrial wastes likely to be received into the sewers by a series of gaugings of the flow in the trunk sewers in 1910.

Discussion of Measurements of Flow in Trunk Sewers.

During April and May, 1910, Mr. George L. Thon of Mr. Alvord's office, made gaugings of most of the sewer outlets. The results of these gaugings are given in Table 33.

The district numbers, gross areas, and sewered areas of the various sewer districts are given for reference in Table 34.

The only sewers in which the flow was not gauged were those in districts 3, 4, 40 and 42. The total of the quantities of sewage found to be flowing at the hours when gaugings were made was at the rate of 82,500,000 gallons per day. This quantity was produced on a total of 10,803 acres of sewered area, and is equivalent to 7,640 gallons per acre per day.

4303

Table 33.

Estimated Quantities of Industrial Wastes from Each District Based on Gaugings and Computations.

District No.	Popul. per acre of sewered area.	Est. of total water supply contributed plus ground water at time of gaugings, gals. per day.	Measured flow of sewage, gals. per day.	Diff. assumed to be max. rate mfg. wastes, gals. per day.	Total mfg. wastes $\frac{\text{No. 5} \times 1.24}{0.7}$, gals. per day.	Total industrial wastes. Gals. per day per acre of sewered area.	Total industrial wastes. Gals. per capita per day.

41	15.4	341,000	132,500	.....	.....	.....	...

55 Applying this quantity to the total sewered area of the city (12,137.3 acres), the corresponding flow of sewage would be at the rate of 92,750,000 gallons per day, which represents the total quantity produced at this time in the day (say between 9 A. M. and 4 P. M.), by all districts, including those which were not gauged.

Assuming that 70 gallons per capita per day of the municipal water supply are delivered to the sewers in the form of sewage, as previously discussed, the present population of 373,857 people would contribute 26,170,000 gallons per day.

April and May are months during which the ground water is generally found to be high, and it would seem to be a conservative assumption that the average leakage during the period covered by these measurements amounted to 37,000 gallons per day per mile of sewers, or 980 gallons per acre per day. (The analysis of measurements of flow in District No. 47 showed 560 gallons per day per acre in October.) While the entire City is not sewered, there is little doubt that the ground water from a larger area than that actually sewered is received into the sewers, and for that reason it is fair to use, in these calculations, the actual area within the City limits (14,374 acres). On this basis the quantity of ground water finding its way into the sewers would be 14,090,000 gallons per day, which added to the water supply contributed, would amount to 40,260,000 gallons per day, as the amount of domestic sewage and ground water.

56 Assuming that the flow of ground water and water supply contributed during that portion of the day within which the guagings were made,—from 9 A. M. to 4 P. M.—was 135% of the average flow for the twenty-four hours, (based on measurements of flow in district No. 47), the flow during this period would be at the rate of 54,350,000 gallons per day. Deducting this quantity from the rate of flow calculated from the gaugings, 92,750,000, there is found to be a difference of 38,400,000 gallons per day, which represents the rate of flow of industrial wastes during these hours of the day.

By far the larger portion of industrial wastes are discharged during ten hours of the day. Assuming that ¾ of the total quantity represents this portion, and that the discharge is uniform during the ten hours, it appears that 16,000,000 gallons (10/24 × 38.40 m. g. d.) is equivalent to ¾ of the quantity produced per day, and that the total quantity would be 21,350,000 gals. per day, equivalent to 57.2 gallons per capita.

The result of these measurements and the calculations based upon them, to the effect that the quantity of manufacturing wastes discharged into the sewers amounts to about 21 million gallons per day, does not seem unreasonable. It should also be remembered that some of the industrial wastes are now discharged into the rivers. Such of these wastes as may tend to seriously pollute the rivers should be diverted from them into the sewers as soon as the intercepters are put into use.

57 The fact that a single industrial plant may discharge as great a quantity of wastes as 3,000,000 gallons per day, equivalent to nearly 10 gallons per capita for the entire population

of the city, is further evidence that an estimate of 60 gallons per capita per day of industrial waste from the entire city is not unreasonable.

Milwaukee is very favorably situated to provide a cheap supply of water for industrial purposes, as plants located near any of the rivers and canals can secure water from them. As soon as the sewage is intercepted this water will be of fairly good quality, and can be used without purification for many of the rougher purposes, and where a water of comparatively high degree of purity is necessary, as for dyeing delicate tints, the river water can be purified locally at comparatively small expense. It seems logical therefore, that Milwaukee should continue to be a favorable location for industries requiring large quantities of water, and that, in estimating the future quantity of sewage to be purified, provision should be made for as great a quantity of industrial wastes as appears to be produced at the present time, and it should further be assumed that, as at present, the industries will be supplied with water largely from wells and from the rivers.

In columns 7 and 8, Table 33, is recorded the quantity of industrial wastes per acre and per capita, respectively, calculated as being produced in the various districts. The calculations have been made for each district, by the method just described in calculating the total quantity of industrial wastes. It will be noticed that in a few of the districts, as for example Districts 1, 17, 18 and 19, the quantity of sewage measured was not in excess of the estimated quantity of water supply contributed and ground water flowing in the sewers at the time the measurements were taken. These districts are, we believe, without exception, residential in character, so that industrial wastes were not to be expected. The quantity of industrial wastes from the different districts varies from 2 to 991 gallons per capita per day. The districts in which this unit quantity is found to be particularly high are those which are known to contain numerous industrial or mercantile houses, and therefore, it is considered that the results of this calculation are reasonable and reliable. The maximum quantity of industrial wastes produced per acre of sewered area was 27,370 gallons per day for District 51. The quantities vary greatly.

58

Summary of Calculations and Estimates of Quantities of Sewage.

Summarizing the foregoing calculations and estimates, the quantity of sewage produced in 19-0 would be made up as follows:

TABLE 35.

Quantity of Sewage, 1910.

	Mil. gals. per day. (1)	Gals. per cap. per day. (2)	% of flow. (3)
Water supply contributed	26.17	70	42.4%
Ground water*	14.09	38	23.
Industrial wastes	21.35	57	34.6
Total	61.61	165	100.0

*When leakage is moderate.

59 This quantity, equivalent to 165 gallons per capita, may be expected for periods of one or two months in the spring, and for periods of several days, possibly a month at a time, occasionally during other seasons of the year. It is probably somewhat above the annual average quantity which will be delivered to the disposal works.

The water supply contributed in the form of sewage is estimated to be 42% of the total sewage flow, and the manufacturing wastes nearly 35%. The quantity of sewage estimated for 1910,—61,610,000 gallons per day,—is 1.58 times the daily average water consumption for the year. It should be remembered that this estimate includes a moderate amount of leakage, though not more than may be expected for one or two months at a time. This estimate is therefore probably somewhat greater than the average quantity of sewage actually discharged into the rivers. It is interesting to note, in this connection, that the quantity of sewage in the North Metropolitan District of Boston, for the years 1904 to 1909 inclusive, was 1.23 times the water consumption.

There will be comparatively short periods of time, say from one to two weeks' duration, during which the quantity of ground water reaching the sewers will be considerably in excess of that included in the foregoing estimate of 61.61 million gallons per day. Assuming that this excess quantity of ground water would be equal to that already included, (980 gallons per acre), the total sewage flow would become 75.7 million gallons per day, equivalent to 286 gallons per capita.

60 Neither of these estimates includes any storm water. The estimates of the quantity of ground water per acre and of manufacturing wastes per capita are uniform throughout the period of forty years considered in this report. The quantity of water supply contributed has been gradually increased as previously explained. The population and the area of the City are increased so that the total quantity of sewage per capita varies from time to time in accordance with the growth of the city and the increase in the quantity of water consumed. The unit and total quantities used in and resulting from these calculations are given in Tables 36 to 37 inclusive.

The basis of design of the works for the clarification or purification of the sewage should be the average quantity of sewage per day when leakage is moderate, which has been estimated at from 165 to 182

gallons per capita, equivalent to 100,000,000 gallons in 1930 and 155,000,000 in 1950, calculated upon the estimated population for those years. Due consideration should be given, however, to the fact that very much larger quantities of sewage will be received in time of storm, and that there will be a material fluctuation in the rate of flow from day to day, and from hour to hour during the day. The capacity of the intercepting sewers, the pumping station and the outfall, cannot be based upon the average quantity of sewage, but must be proportioned according to the maximum rate of flow to be provided for.

In tables 38 and 40 are given the estimated maximum rate of flow in gallons per capita, and in million gallons per day.

61 Column 2, Table 38, gives the estimated maximum rate at which the water supply will be contributed to the sewers. It is obvious that the quantity of ground water will not vary from hour to hour during the day. It has already been explained that the maximum rate of domestic sewage flow will be about 135% of the average rate.

From Table 37, it is seen that in 1910 the estimated sewerage water supply contributed is 70 gallons per capita, and the leakage 38 gallons per capita. The total of these two items would, therefore, be 108 gallons per capita, which represents the average quantity of domestic sewage. This would be increased to 135% at times of maximum discharge, the quantity then being about 146 gallons. Deducting the ground water, 38 gallons, we have the maximum rate at which the water supply is contributed,—108 gallons per capita per day.

It has been assumed that three-quarters of the industrial wastes will be discharged in ten hours, so that the maximum rate of discharge will be 103 gallons per capita, (column 3, Table 38). Adding the maximum rate of water supply contribution, the maximum rate of industrial wastes and the leakage when moderate, it appears that in the year 1910, the estimated maximum rate of total sewage flow will be 248 gallons, and in 1950, 271 gallons per capita per day. At times when the leakage into the sewers is excessive, the maximum rate of flow is estimated to be 285 gallons and 312 gallons per capita per day in 1910 and 1950 respectively.

62 From the foregoing discussion, it is evident that if the intercepting sewers are to have a capacity sufficient for a population of 850,000 people, as estimated for 1950, they must provide for a maximum rate of flow of 312 gallons per capita daily. It is realized that these estimates are based upon somewhat unsatisfactory data, and no provision whatever is made for storm water. In view of the advisability of continuing the flushing of the rivers, and the practical impossibility of preventing the bacterial infection of the waters of the bay, and possibly the water supply, it does not seem wise to provide for the pumping, clarification and disposal into the Lake at the new outlet, of a material proportion of the storm water. It has, therefore, been decided not to attempt to collect in the intercepting sewers, large quantities of storm water, but to provide liberally for the maximum rate of flow at times when the leakage into

the sewers is excessive. Accordingly, the capacity of the interceptors has been based on an estimated flow at such times of 350 gallons per capita, or 38 gallons in excess of the estimate for 1950, given in column 7, Table 38. The quantity of sewage for which provision is made, will therefore, be 297,500,000 gallons daily (350 gallons per capita from a population of 850,000 people).

While no provision is made for storm water after the city reaches a population of 850,000, it is obvious that from the time the interceptors are built until this population is reached, there will be a surplus capacity which will be available for storm water. In
63 times of moderate flow, as during the warmer months of the year, the amount of this surplus capacity will be that given in Column 3, Table 41.

1910..	40.16	38.45	14.09	92.70	28.18	106.80
1920..	53.23	48.90	19.12	121.25	38.24	140.40
1930..	67.65	60.20	24.20	152.05	48.40	176.20
1940..	87.48	73.60	29.22	190.30	58.44	219.50
1950..	108.90	87.50	34.30	230.70	68.60	265.00

TABLE 41.

Surplus Capacity of Interceptors Available for Carrying Storm Water.

(Capacity of Interceptors 297.5 Million Gallons per day.)

Year.	Avg. rate of sewage flow when leakage is moderate (m. g. d.).	Surplus capacity of interceptor (m. g. d.).	Dilution of sewage at time overflow takes place.
(1)	(2)	(3)	(4)
1910	61.61	235.89	1 :3.83
1920	80.73	216.77	1 :2.68
1930	101.40	196.1	1 :1.93
1940	127.22	170.28	1 :1.34
1950	155.15	142.35	1 :0.92

It is therefore apparent that, for many years, comparatively large quantities of storm water will be collected by the intercepting sewers, and can be passed through the clarification works and discharged through the outfall sewer.

From table 41, it appears that the quantity of storm water which can be carried, were the sewers completed in 1910 would be 3.83 times the average flow of sewage when leakage is moderate; whereas in 1950, the quantity of storm water at such time would be nearly equal to the quantity of sewage. The dilution of sewage with storm water at the time of overflow would be increased or decreased as the quantity of sewage flowing at the time was less or greater than the average quantity.

The foregoing estimates of the quantity of sewage which will be produced have been made as the basis of design of sewers and disposal works. For calculations of operating conditions it may be desirable to use the annual average quantity of sewage which will probably be about 130 gallons per capita.

1 COMPLAINANTS' EXHIBIT No. 177. James D. Maher, Commissioner.

In the Supreme Court of the United States, October Term, 1912

No. 5, Original.

THE UNITED STATES OF AMERICA, Complainant,
vs.
THE PEOPLE OF THE STATE OF NEW YORK and JOHN E. ANDRUS et al.

Motion to Dismiss Bill Without Prejudice.

Now comes the Solicitor General on behalf of the complainant in the above-entitled case, and filing herewith a stipulation between the parties by which a settlement of the questions involved has been made, which settlement provides in paragraph seven (7) that said stipulation shall be filed in this Court and that the bill of complaint be dismissed without prejudice, moves the Court to dismiss said bill of complaint without prejudice.

(Signed) WM. MARSHALL BULLITT,
Solicitor General.

December 2, 1912.

2 In the Supreme Court of the United States.

In Equity.

THE UNITED STATES OF AMERICA, Complainant,
against
THE PEOPLE OF THE STATE OF NEW YORK and JOHN E. ANDRUS, William Archer, and John J. Brown, as Commissioners of the Bronx Valley Sewer, Defendants.

Stipulation.

Two years before the Bronx Valley Sewer was completed to the margin of the Hudson River or in any way put into use, the United States instituted the above cause in order to prevent the further defilement of that stream by the discharge from said sewer. With full notice of the claims set up and relief asked therein, the Commissioners named as defendants caused the sewer to be constructed to a point beneath the waters of the river some 20 feet from the Eastern bank; and for a time they allowed sewage to be received into and discharged therefrom. Such use of the sewer was enjoined in a proceeding instituted in the Supreme Court of New York for the County of Westchester by the Leak & Watts Orphan House, &c., in June, 1911. The United States has continuously objected to the proposed sewer;

and at all times has refused to assent to the construction of the same beyond the bulkhead line unless and until adequate provision should be made for the purification of the effluent.

After this cause was instituted, the terms of office of Commissioners Andrus, Archer and Brown, terminated; and under the pro-
3 visions of Chapter 361, Laws of New York for 1911, the undersigned, Frank Jerome Hoyle, Henry C. Merritt and John L. Hayes, were appointed. The latter now constitute the full membership of the Bronx Valley Sewer Commission and may rightfully exercise all its powers.

In order to end the present controversy and to secure permission to complete the sewer beyond the bulkhead line as was originally contemplated, and with the desire on the part of the United States ultimately to bring about adequate purification of the Hudson River, the following stipulation and agreement has been entered into by and between the United States and Frank Jerome Hoyle, Henry C. Merritt and John L. Hayes, as members of the Bronx Valley Sewer Commission, acting in behalf of themselves and of their successors in interest and control:

First. The Bronx Valley Sewer Commissioners at once will begin the installation of a plant for the partial purification of the effluent of the Bronx Valley sewer system by screening and sedimentation with an efficiency sufficient to remove and which shall at all times remove from said effluent enough of its putrescible contents to purify the same to the extent of 10% upon an absolute putrescibility scale. This plant shall be completed and put into operation on or before the first day of May, 1913; and it or one not less efficient shall be kept in continuous operation producing at least the results above specified so long as the Bronx Valley sewer continues in use.

Second. At all times during the operation of the Bronx Valley sewer system, in addition to those specified in the paragraph immediately above, the requirements enumerated under the seven heads immediately following will be met either through the plant and installations above called for or through requisite additional arrangements:

(1) There will be absence in the Hudson River of suspended particles visible to the naked eye coming from the effluent of said sewer.

(2) There will be absence of deposits in the waters of the Hudson River coming from the effluent of said sewer which the Secre-
4 tary of War of the United States, exercising a reasonable discretion, may find objectionable.

(3) There will be absence in the waters of the Hudson River and its vicinity of any odor due to the putrefaction of organic matter contained in the effluent of said sewer which the Secretary of War, exercising a reasonable discretion, may find objectionable.

(4) There will be a practical absence on the surface of the Hudson River, at the dispersion area or elsewhere, of any grease or color due to the discharge of said sewage.

(5) There will be no public or private nuisance occasioned by the discharge from the said sewer.

(6) The effluent from said sewer shall not injuriously affect property of the United States situated in the Hudson River.

(7) There shall be excluded from the sewer all refuse matters of the classes forbidden by law to be discharged into the navigable waters of the United States.

Third. At any time subsequent to January 1st, 1917, or to the date when there shall be 50,000 persons contributing sewage to said sewer,—whichever date first arrives—the Secretary of War of the United States may designate a board of three men, which shall make inquiry into the pollution of the Hudson River by the presence therein of sewage, filth and refuse matter, and upon a view of the facts and circumstances thought to deserve consideration, this board shall determine and thereafter report to him what, if any, purification of the effluent of the Bronx Valley sewer, in addition to that specified in the foregoing sections of this stipulation and irrespective of what others in fact may be doing towards bringing about the end desired, ought to be required in order to impose upon said sewer, its managers and the territory served by it, the performance of their just, fair and equitable part of whatever may be necessary for the restoration and maintenance of the waters of the Hudson River to and in such degree of purity as will render them adequate for the support of the life of shad and other major fish.

After receiving the report of this board, the Secretary of War may, from time to time, direct such further degree of purification of the effluent of the Bronx sewer not in excess of the findings of the board as he may think proper; and within two years after receiving any such direction, the Bronx Sewer Commissioners or their successors in control shall cause the same to be brought up to the required standard.

The board of three appointed by the Secretary of War shall include one member designated by the Bronx Sewer Commissioners or their successors, provided he be named within thirty days after request therefor, and provided further that all expenses incident to his service shall be borne by those in whose behalf he is designated. A majority of the board may act and a report concurred in by two members shall be the report of the board.

Fourth. At all times hereafter, through such representatives as he may designate, the Secretary of War of the United States shall have full opportunity to inspect the construction of the proposed purification plant and the condition and working of the entire sewer system, in order to determine whether the terms and provisions hereof are being observed in all respects; and to this end the Commissioners will render such expert or other assistance as he may request. Said Secretary at all times shall have the right to decide whether such terms and provisions are being complied with; and upon notice from him that they are not, the Commissioners or their successors shall forthwith do whatever may be necessary in order to effect compliance herewith.

Fifth. Full compliance at all times with the terms and requirements of this stipulation shall be and remain the express condition of any permits issued by or on the part of the United States

for the construction and future maintenance and operation of the Bronx Valley sewer or any part thereof.

Sixth. This stipulation shall not become effective unless and until all such permits as may be requisite under the statutes of the United States for the construction, maintenance and operation of said sewer, according to the plans and specifications heretofore prepared, are actually obtained nor unless or until such permits are made conditional upon the compliance at all times with all the terms hereof.

Seventh. As soon as the permits contemplated in the section immediately preceding have been issued and this agreement, properly executed, has been filed in the office of the Clerk of the Supreme Court as a stipulation between the parties in the above-entitled cause, the United States will cause the bill of complaint to be dismissed, but without prejudice.

Eighth. Nothing herein contained shall hinder or interfere with the assertion or execution by the United States of their rights and powers granted by the Constitution or Statutes.

In witness whereof, this instrument has been duly executed in triplicate, being signed in the name and on behalf of the United States by the Attorney General and by all the members of the Bronx Valley Sewer Commission and being sealed also on behalf of said Bronx Valley Sewer Commission with its seal attested by its Secretary—all on the 17th day of July, 1912.

THE UNITED STATES OF AMERICA,
(Signed) By GEO. W. WICKERSHAM,
Attorney General.

[SEAL.] THE BRONX VALLEY SEWER COMMISSION,
(Signed) By FRANK JEROME HOYLE,
(Signed) JOHN L. HAYES,
(Signed) HENRY C. MERRITT.

Attest:

(Signed) JAMES J. SHAW, *Secretary.*

Endorsed: Supreme Court of the United States. The United States of America, complainant, against the People of the State of New York, and John E. Andrus, William Archer and John J. Brown, as Commissioners of the Bronx Valley Sewer, defendants. Stipulation. Supreme Court U. S., October Term, 1912. Term No. 5, Original. The United States of America, complainant, vs. The People of the State of New York et al. Motion and stipulation to dismiss bill of complaint. Filed December 2, 1912.

Dr. W. J. O'Sullivan, Asst. Corporation Counsel, Hall of Records, City.

DEAR SIR: We respectfully submit our report upon the pollution of the harbors of those cities visited by your Committee during the month of December 1911.

The descriptions of the cities which follow are purely of an introductory nature, and are purposely made as brief as possible, and contain but very little data with relation to population, sewage flow, and information of like character, as all of these data, as well as other data relating to our investigations, are contained in the tables and statistics which follow.

General Description of Cities and Harbors.

Havana.

The City of Havana, Cuba, is built upon a peninsula and in relation to the Gulf of Mexico and its harbor, is located practically as shown on the accompanying map.

The old city, covering an area of some 1,500 acres, is but little above sea level, but the newer city and suburbs, covering about 4,500 acres, are hilly and reach, at some points, an elevation
2 of 130 feet above mean tide. The population is 360,000.

The waters of the harbor have a tidal range of about one foot between high and low water. The entrance to the harbor is through a narrow channel about 1,200 feet wide and about one mile in length. The area of the harbor is approximately 15,000 acres, giving a tidal displacement of approximately 65,000 cubic feet.

At the present time a complete system of sanitary sewers is being constructed for the entire city, which, when completed, will collect the sewage of the city and discharge it into the Gulf of Mexico at a point 4,000 feet east of Moro Castle in 30 feet of water.

At the present time the lateral system has been almost completed, and the sewage of the city, and suburbs tributary to the harbor, discharges through these new sewers and some old sewers that have not yet been intercepted.

At the time of our inspection, therefore, the sewage of the population tributary to the harbor was being discharged through outfalls along the water front. The aggregate population thus discharging sewage was, according to the estimate obtained from the Obras Publicas, approximately 87,000. Of this population, some 40,000 were discharging sewage through sewers at scattered points along the water front facing the main harbor, and where the tidal dilution and dispersion were relatively great.

The remainder of the population connected with sewers, approximating 47,000 people, were discharging their sewage into the
3 section of the harbor known as Atares Bay, an arm of the harbor lying at its extreme southwestern limit. Matadero Creek, St. Nicholas Creek, Dulce Creek, and other small creeks, draining a considerable portion of the suburban area of the city, empty into Atares Bay, and sewers of large size discharge into these.

It was to this latter section of the harbor, where objectionable conditions were very marked, that our observations and studies were largely restricted.

The accompanying map shows the location of the city with relation to that part of the harbor which was under observation.

The chief data relating to Atares Bay, as well as to portions of other harbors observed by us, are given in Tables Nos. 1 and 2, which follow.

The map shows the limits of pronounced and obnoxious visual sewage pollution, and the less marked but plainly visible sewage pollution.

(Here follows map of Baltimore harbor, page 4.)

Exhibit 178

Limit of Area considered in Estimating Dilution.
BALTIMORE
NORTH WEST HARBOR
PATAPSCO RIVER
-BALTIMORE HARBOR-
BALTIMORE, MD.

5 Baltimore.

The City of Baltimore, Md., is situated at the mouth of the Patapsco River, which empties into Chesapeake Bay, 160 miles from the Atlantic Ocean.

The city covers an area of approximately 19,200 acres, of which about 9,600 acres are densely built up. Its elevation varies from high tide at the docks to about 450 feet above mean low tide in the suburbs. Its population is 558,000.

The present sewer system consists of a number of storm water drains, entering into Jones Falls, Gwynns Falls, and the North West Harbor.

The sanitary sewage from about fifty per cent of a population of 290,000, in the more densely built up portion of the city, is carried by these drains into Jones Falls and the North West Harbor, with the result that they have become little better than open sewers, or cess pools, excessively offensive to sight and smell. The remaining fifty per cent of the population in the denser portions of the city here considered, is served by privy vaults and cess pools. The small per cent of population in other parts of the city connected to sewers, drains into Gwynns Falls and the Patapsco River.

The city is at present constructing an extensive system of sanitary sewers, designed to remedy the exceedingly bad conditions now obtaining in the North West Harbor.

The portion of the harbor and tidal area considered in this report in estimating sewage dilution is shown in blue on the accompanying map.

The tidal area of the North West Harbor is approximately 819 acres, and the tidal range is 1.2 feet. For details, see Appendix 1, Page 52.

(Here follows map of New York harbor, page 6.)

In this report, that portion of New York City and the surrounding communities is considered, the sewage from which empties into the Upper Bay. These communities are as follows:

Communities in the State of New Jersey Now Discharging Sewage ley Sewerage District.

Passaic County:

Paterson.
Manchester.
Prospect Park.
Hawthorne.
Aquackononk.
Passaic.

Bergen County:

Glen Rock.
Saddle River.
Midland.
Garfield.
Lodi Borough.
Hasbrouck Heights.
Woodridge.
Wallington.
Carlstadt.
East Rutherford.
Rutherford.
Union.
North Arlington.

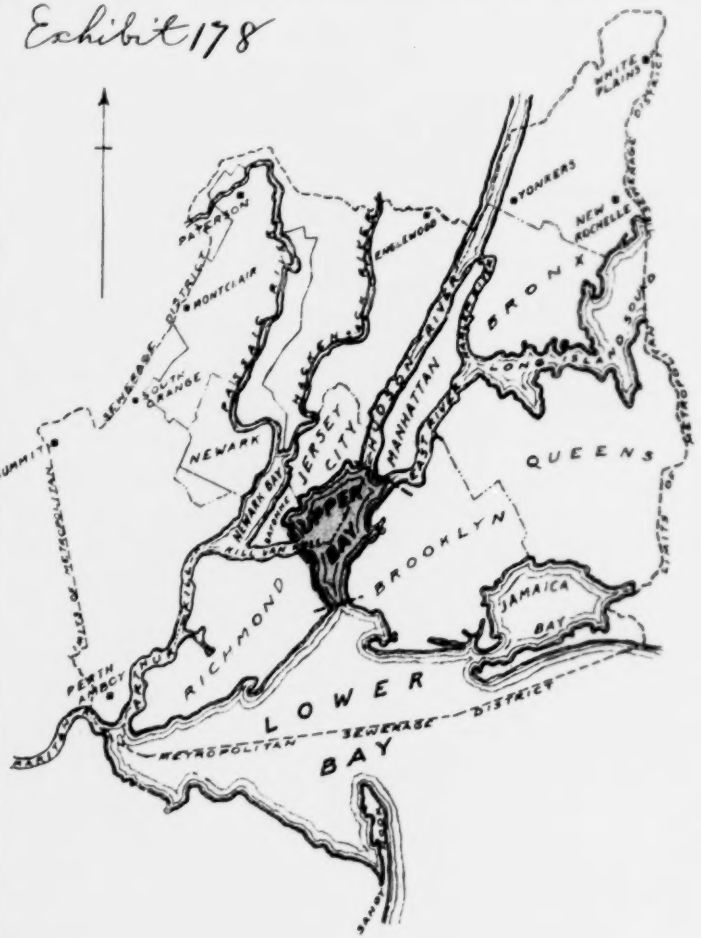
Essex County:

Nutley.
Newark.
Belleville.
East Orange.
Bloomfield.
Glen Ridge.
Montclair.
Orange.

Hudson County:

Harrison.
East Newark.
Kearney.

Communities in the State of New Jersey, now Discharging Sewage Into the Hackensack River, Within the Metropolitan Sewerage District.



Hudson County:

Jersey City.
Kearney.
North Bergen.

Bergen County:

Fairfield.
Ridgefield.
Cliffside Park.
Palisade Park.
Maywood.
Lodi Township.
Hasbrouck Heights.
Little Ferry.

Bronxville.
Mt. Vernon.
Bronx Borough.
Manhattan Borough.
Part of Brooklyn Borough.
" " Queens "
" " Richmond "

Communities in the State of New York Now Discharging Sewage Directly Into Newark Bay and the Arthur Kill.

Part of Richmond Borough.

It has been assumed that 80 per cent of the population within these communities contributes domestic sewage to the various drainage systems.

As it has been determined by the United States Coast and Geodetic Survey, and so reported by the Metropolitan Sewerage Commission, and the Central Committee of Experts for the State of New York that approximately 84 per cent of the water entering Newark Bay finds its way through Kill Van Kull into Upper New York Bay, the remaining 16 per cent going through Arthur Kill into Lower New York Bay, we have, for the purpose of estimating, assumed that but eighty-four per cent of the sewage, draining into the Passaic and Hackensack Rivers and into Newark Bay, reaches Upper New York Bay.

In other words, we have considered that all of the sewage which enters the Hudson and East Rivers, and Upper New York Bay, together with eighty-four per cent of the sewage reaching the Passaic, the Hackensack and Newark Bay, is contributary to Upper New York Bay. If the Passaic Valley Trunk Sewer is constructed, then, of course, one hundred per cent of the sewage from the Passaic Valley Sewerage District will be delivered directly into the Upper New York Bay in the vicinity of Robbins Reef Light.

The elevation of the district considered varies from high tide at the docks to about three hundred feet above mean tide in East Orange and White Plains.

The sanitary and combined sewers within this district discharge directly into the streams or bays tributary to the Upper New York Bay, or into the Bay itself. Many outlets are under piers at the bulkhead line. These outlets are so numerous, however, that it is impossible to show them in the accompanying map, which displays the boundary of the district contributing sewage and the tidal areas considered in estimating dilution. For the purpose of estimating the dilution we have taken the total quantities of new sea and land water available in Upper New York Bay as explained in the Appendix.

(Here follows map of Potomac River at Washington, D. C., page 10½.)

Exhibit 178

- POTOMAC RIVER -
AT
WASHINGTON, D.C.

11 Washington.

The City of Washington is situated on the north bank of the Potomac River 156 miles from the entrance into Chesapeake Bay, and 185 miles from the Atlantic ocean. The Potomac at this point is quite a bold stream, draining an area of over 11,000 square miles.

The city has an area of approximately 6,400 acres tributary to the sewage system. It rises from the river level to an elevation of about 90 feet above mean tide. Its population is 343,000.

The city is almost completely sewered and is served with an extensive general system of combined sewers. The sanitary sewage of approximately 308,000 people is taken care of by the general sewerage system and is pumped to an outlet near the east bank of the Potomac River, three miles below the city, to which point the storm water drainage is also pumped.

The sewers in certain small districts discharge directly into the Potomac at several points along the water front.

The outlet of the general sewerage system consists of two 60 inch pipes, opening vertically at a depth of 28.7 feet below mean high tide, and at a distance of 750 and 800 feet respectively from the river bank. The location of these outlets is indicated by a red dot upon the accompanying map. The sewer outlet is carried well out into the main shipchannel where the currents in the river have the greatest velocity.

12 Washington is located at the head of tide water, the tidal range being 2.9 feet. The fresh water dilution is so great that the sewage may be considered to empty into a fresh water stream.

Notwithstanding the very slight difference in density of the sewage and river water, the vertical rise of the sewage was rapid, judging from the surface effects, at the time of our visit, and although the sewage was partially screened, the visual evidence of the sewage in the form of particles of feces, match sticks, paper, etc., were apparent for a mile or more north of the outlet. The observed sewage field is indicated on the accompanying map. The turbidity of the Potomac water at the time the observations were made was sufficient to materially lessen the visual effects which would result in clear water.

The observations herein reported were limited to a study of the outlet just described, and the estimated tidal dilution is considered to be the average annual daily fresh water flow of the Potomac River at this point.

(Here follows map of Tampa harbor, page 13.)

14

Tampa.

The City of Tampa, Florida, is situated at the northern extremity of Hillsboro Bay, the eastern arm of Tampa Bay on the west coast of Florida, and 35 miles from the Gulf of Mexico.

The main outlet of the sewer system is a horizontal pipe, six feet in diameter, opening at the edge of a dock near the mouth of the Hillsboro River and nine feet below mean tide. This outlet delivers the sewage of about 10,000 people of a total of 13,000 connected with sewers in the City of Tampa.

There are two other outlets emptying into the Hillsboro River, which serve approximately 3,000 people.

Our observations were confined practically to the main outlet.

The limits of the tidal area considered are shown on the accompanying map. This area is approximately 134 acres. The tidal range is two feet.

The conditions of the main outlet in Tampa were peculiarly interesting as they offered an excellent opportunity for observing the rapid rise of fresh water sewage in strongly saline waters. The salinity of the water near the point of the main outlet was 14,409 parts per million.

The sewage flowing from this outlet rose at once to the surface, boiling up above the surface of the surrounding water, forming a mushroom shaped mound, distributing sewage over an area ten feet in diameter, which floated down stream on the surface of the tide, spreading out in fan shape, as it progressed downstream.

15 For a distance of 100 feet below the outlet, the water showed a very marked sewage color, and had an offensive odor and marked discoloration, and more or less dissipated floating feces and sewage matter were noted at a distance of 750 feet below the outfall.

● = Sewer Outfalls.-
= Limits of Area considered in Estimating Dilution.-
D = Approximate Zone of Visible Pollution.

17 **Boston.**

The City of Boston, Mass., is situated at the mouth of the Charles River, at the head of Boston Harbor on the coast of Massachusetts.

The territory about Boston, considered in this report, comprises the "Boston Metropolitan Sewerage District" and the "Boston Main Drainage District," and has a total area of approximately 206 square miles. Its elevation varies between the tide water at Boston, and 500 feet above mean tide at the headwaters of the Charles River.

The sewage from the densely built up portion of Boston is collected by the sewers of the "Boston Main Drainage System," and is pumped to tanks on Moon Island, where it is stored until the tide is ebbing, when it is discharged into the harbor, producing a clearly marked area of greasy, sewage colored water. The sewage from the surrounding communities is collected by the sewers of the "Boston Metropolitan Sewerage District." This sewage is discharged into the harbor at Deer Island and Peddock's Island, as indicated on the accompanying map. This map displays also the tidal area considered in estimating sewage dilution and the limits of the "Boston Metropolitan Sewerage District" and the "Boston Main Drainage District." It also indicates the visual field of sewerage pollution as derived from the report of the Massachusetts State Board of Health for the year 1900.

Boston Harbor has been the subject of much study by the Massachusetts State Board of Health, a special report having been made thereon in 1900 by Mr. Goodnough as Chief Engineer.

18 Again, in 1905 Mr. Goodnough made a second report, as published in the Report of the Massachusetts State Board of Health for that year.

The facts which are given in this report are largely quoted from the data contained in the two reports of Mr. Goodnough and from the published reports of the Metropolitan Water and Sewerage Board for the years 1905 and 1910.

Your Committee did not visit Boston, but the facts as set forth have been collected for the purpose of comparing conditions in Boston with those in New York Harbor.

(Here follows map of Savannah River at Savannah, Ga., page 19.)

20 Savannah.

The City of Savannah, Georgia, is situated on the south bank of the Savannah River, 18 miles from the mouth.

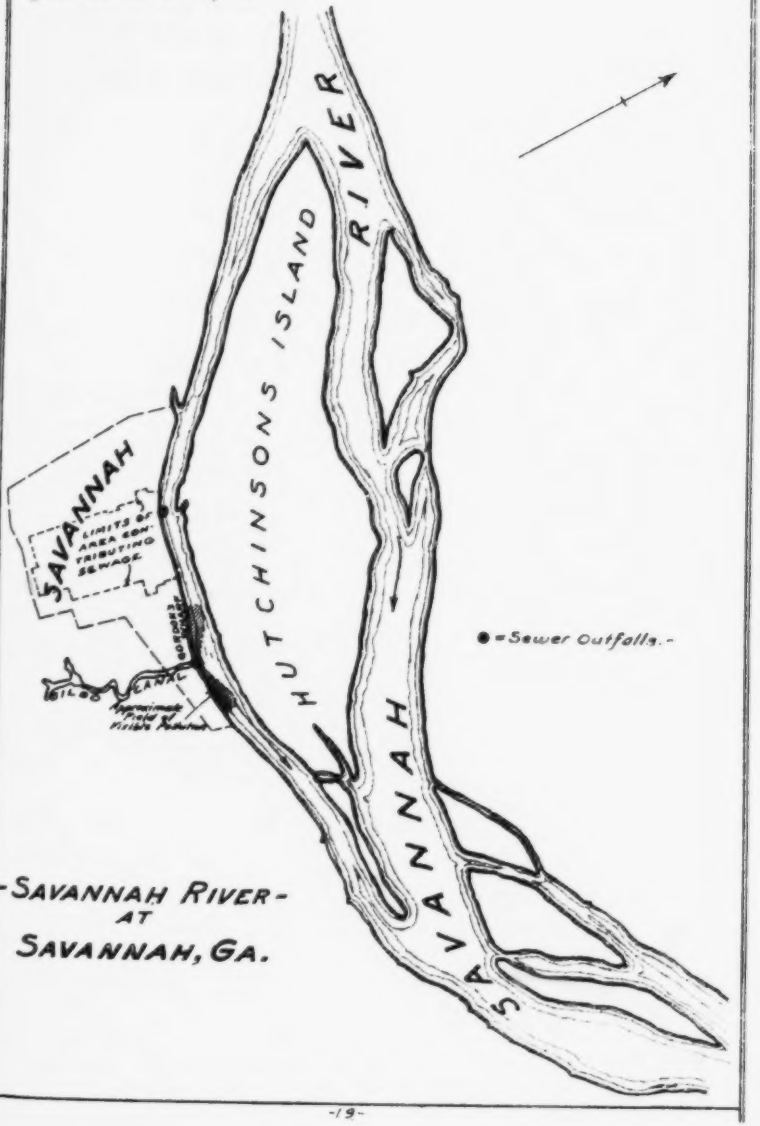
That portion of the city tributary to the sewer system covers an area of 1,220 acres, and includes the densely populated sections.

It is built upon low land, its highest point having an elevation of but 52 feet above mean low water in the river. One half of the area of the city has an average elevation of only 35 feet above mean tide.

There are 51 miles of sanitary sewers, emptying into the Savannah River at two points. The principal outlet is at Gordon's Wharf and is a 30-inch horizontal pipe ending at the wharf line and 13 feet below mean low water. These sewers serve only about three-quarters of the population. The remainder use privy vaults and dry closets. At the present time, however, there is a movement on foot to extend the sewer system to the outlying districts.

An examination of the river at Savannah during flood tide on January 12, 1912, showed no visual evidence of sewage pollution, the river appearing generally clean, though turbid.

Of all the harbors visited by your Committee, Savannah afforded the best opportunity of studying the effects of turbidity upon the visual surface nuisance to be observed in the vicinity of sewer outfalls. It was plainly evident that high turbidity appreciably reduced visual effects, so much so that it was difficult to observe the sewage immediately at the outfall at high tide. The high turbidity of the water in the Savannah River, coupled with its low specific gravity, accounts for this condition.



21 The salinity of the water here, as in Washington, is very low.

At slack tide, the sewage rises to the surface at a point 50 feet north of the pier line, and on ebb tide evidences of the sewage were observed for a distanc of 1,600 feet down stream from the outlet.

The owner of the boat from which these observations were made, as well as a fore man on the wharves, stated that under the piers, in summer, the stench of sewage was very noticeable for an appreciable distance each side of the sewage outlet.

The tidal velocity in this stream is very high at the center of the river, and, as has been observed, in the case of New York Harbor, the tidal velocity along the shore lines is very much reduced by the piles and other obstructions sustaining the piers. The result is that in Savannah, as in New York, the sewage flows in a line parallel with the axis of the river and hugs closely to the shore. Under these conditions, it is but natural that there should be a heavy deposition of suspended matter under the piers, and no doubt, if the Gordon Street outlet could be observed in warm weather, septic action of the bottom mud would be noticed for an appreciable distance each side of this outlet.

Exhibit 178

-SAVANNAH RIVER-
AT
SAVANNAH, GA.

The accompanying map shows the location of the sewer outlets. Savannah, as in the case of Washington, was considered as having only that dilution produced by the fresh water flow of the river. The Savannah River drains an area of approximately 11,000 square miles above its sewer outlet.

(Here follows map of St. John's River at Jacksonville, Fla., page 22.)

23 Jacksonville.

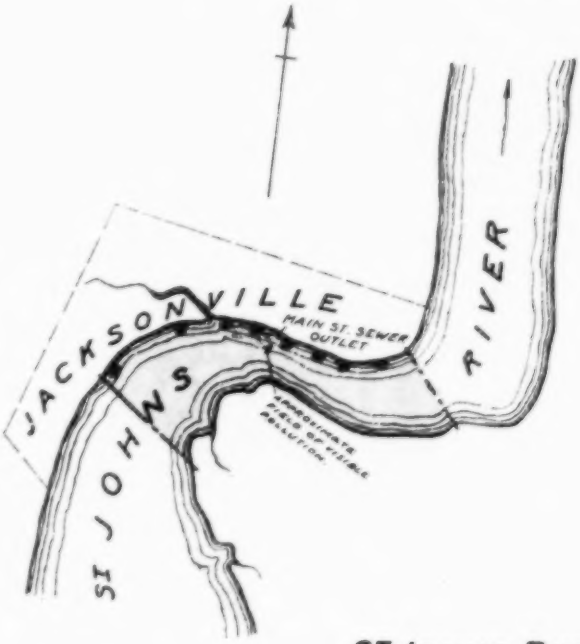
Jacksonville, Florida, is situated on the north bank of the St. John's River at a bend 22 miles above its mouth. The St. John's drains an area of 8,143 square miles above Jacksonville.

The city is not closely built up, and covers a considerable area at an elevation of from 0 to 43 feet above the river.

There are sixty-seven miles of sewers, principally sanitary, leading to eight outfall sewers, as follows, reading from east to west on the accompanying map:

Fairfield Outfall.
Georgia Street.
Catherine "
Market "
Main "
Cedar "
Stonewall "
Osceola "

At the Fairfield outfall, the sewage is pumped out under head. To the others, the sewage flows by gravity to outfalls at a depth of from 4 to 20 feet below the water in the river and are horizontal with the exception of the Market Street and Stonewall Street sewers, which are turned down. In size, they range from 8 to 24 inches in diameter.



These sewers serve about one-half of the population, the remainder being provided with privy vaults or dry closets.

The position of these outlets is indicated at ebb tide by an area of discoloration of the river water, and at the Main Street outlet by noticeable boiling. At the Catherine Street outlet, which was located at the pier head, there was visible evidence of septic action in the bottom mud for an area one hundred foot square, to-
24 gether with a distinct sewage odor, though the temperature of the water at the time of inspection was but fifty-five degrees.

Our observations at Jacksonville were confined chiefly to the Main Street sewer, the largest and most important of the local sewers. This sewer discharges about three million gallons daily. It has a 24 inch horizontal outlet placed about 20 feet below mean tide. The sewage was plainly visible at the surface and the visible sewage field adjacent to this sewer is indicated on the accompanying map. The map also shows the limits of the tidal area considered in estimating the dilution at Jacksonville.

(Here follows map of Charleston harbor, page 25.)

26

Charleston.

The City of Charleston, South Carolina, is situated on the southern point of a low peninsula washed on the east by the Cooper River, and on the west by the Ashley River. To the south, Charleston Harbor extends 6 miles to the Atlantic Ocean.

The area of the built-up portion of the city is 7,680 acres, and its average elevation is about 15 feet above mean tide.

The sewer system at the present time consists chiefly of certain tidal drains to which connections have been made by a small number of houses. In the southern end of the city there are about five or six miles of sanitary sewers, which are now in use. The city is at present, however, engaged in the construction of a general system of sanitary sewers.

The total number of houses in Charleston is approximately from eight to ten thousand, and the number of privy vaults, or dry closets, five to seven thousand, so that possibly not more thar three thousand houses are connected up with existing sewers and drains.

The sewer system will comprise some fifty miles of sanitary sewers, which will empty into the Ashley and Cooper Rivers along the water front.

At the time of our inspections no evidence of pollution was observed in the harbor, except local nuisance in the immediate vicinity of the outlets.

The tidal drain leading into Gadsden Creek was closed at the time of our visit. This creek drains a large marsh, and in going through the marsh in a row boat, the visual evidences of
27 sewage pollution were very marked and there was an appreciable odor of sewage everywhere prevalent. No doubt, this marsh is a source of considerable nuisance in warm weather.

This condition offers a very excellent illustration of the broad local nuisance produced by emptying sewage, even in small amounts, into shallow waters exposed to the full effects of the sun, a condition which was brought prominently to attention on the old Potomac flats prior to the reclamation of the island now forming Potomac Park, and the construction of the main sewer outfall at its present location three miles below Washington. Formerly, the sewage of Washington was carried into the Potomac River at various points along the shore front, and on the flood tide would spread upon the flats where the suspended matter was quickly deposited. With the receding tide, this organic matter was exposed to the influence of the sun, the result being that the foul smelling odors carried by southerly winds were plainly marked at distances as far north as the White House.

The accompanying map shows the location of sewer outlets and the area considered in estimating dilution.

(Here follow Table No. 1 and Table No. 2, pages 28 *a* and 28 *b*.)

29 Relative Effects of Pollution in Different Harbors.

Basic Data.

Tables Nos. 1 and 2 give in condensed form the basic data from which Table No. 3, which follows, was compiled. The basic data for, and explanation of Table No. 1 will be found in Appendix No. 1 and similarly for Table No. 2 in Appendix 2.

Table No. 3 shows the relative degree of pollution in the various harbors considered in the report, the resulting dilution, the per cent of saturation of dissolved oxygen, and the putrescibility of the harbor mud, together with an estimate of the number of tons of wet sewage sludge per million cubic feet of total water (fresh and salt) available for dilution.

Averages Used.

For the purpose of avoiding complication, and in order to obtain a clear conception for a broad general estimate of the permissible pollution of harbors, figures for average tidal range, average rainfall and runoff, and average sewage flow have been used throughout.

Dilution.

The sea water available for dilution (Col. 5, Table 3) in Upper New York Bay is the new sea water which does not return on the next succeeding tide as computed by Mr. H. de B. Parsons in his brief report on "The Tidal Actions in the Harbor of New York." The figures given by Mr. Parsons are substantially those used by the Metropolitan Sewerage Commission. To this was added the new land, or fresh water, as estimated by the same authorities, and approved by the Central Committee Experts.

(Here follows Table No. 3, page 29½.)

(Schedule No. 9 (1))

TABLE No. 3.

RELATIVE EFFECTS OF SEWAGE POLLUTION IN VARIOUS HARBORS.

Harbor	(Local Water) Surface Area in Square Miles of Area in 12 Hours	Rate of Sewage Influx in Millions of Gallons per 12 Hours	Resulting Local Water Dilution	Sea Water Conveyed Available for Dilution in Millions of Gallons per 12 Hours	Total Dilution Assumed as (Local Water Dilution) plus (Sea Water Dilution)	Dissolved Oxygen % Saturation	Permeability of Harbor Mouth (Miles)	Mid Shore Tides per Day	Mid Shore hours per Day of Flood per Cent
(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)
HAVANA	0.5	0.55	1: 09	6.0	1: 11	0.0	1: 2200	66	44.6
NEW YORK (1907)	180.0	138.00	1: 9	2340.0	1: 26			18972	6.0
BALTIMORE	25	1.75	1: 14	43.4	1: 20	23.4	1: 834	304	6.0
NEW YORK (1910)	180.0	55.4	1: 21	2340.0	1: 61	67.0	1: 720	8436	3.4
WASHINGTON	30.0	4.5	1: 111	0.0	1: 111	82.0		492	1.3

CHARLESTON	10.0	0.18	1: 572	53.6	1: 3624	96.0		28	0.1

30 The method of estimating the quantity of water available for dilution used by Mr. H. de B. Parsons, is as follows. See his "Brief Report on the Tidal Actions in the Harbor of New York."

"The quantity of 'new' sea water entering Upper Bay is:

	In million cubic feet per tidal cycle.
At the Narrows—Average for year	2,210
Least amount—(February)	670
Least amount—(Summer—August)	1,520

"These figures were determined,

1st. From observation of the total tidal flow through the Narrows at ebb tide.

2nd. From daily observation by the salinometer, the records covering a period of over one year as made by the Metropolitan Sewerage Commission. The average of these observations is appended.

"If no land-water entered the harbor, then the water in the harbor would be as salty as that of the sea. The mean quantity of water flowing on ebb tide was divided into land and sea-water by means of the salinometer percentages. The land-water was then divided into 'land-water which will return' and 'land-water which will not return.' The latter was taken as the run-off of the rivers for 12 lunar hours and the former as the remainder of the total land-water as shown by the salinometer.

"The sea-water, as shown by the salinometer was then divided by making the 'sea-water which will not return' the same proportion of the total sea-water as the 'land-water which will not return' is to the total land-water. This is so because the land and sea-water are mixed, and the amount of 'land-water which will not return' will take with its proportionate amount of sea-water.

"The division of water on flood tide was made by taking the total volume of flow on flood and laying off the amounts of land and sea water which will return as shown on ebb. The remainder is the 'new' sea water, or the water which was not in the harbor on the preceding tide. It must be equal to the 'sea water which will not return' as given on ebb.

"The land water as shown by the salinometer is always in excess of the runoff. This is so because the flushing action of the harbor is not complete, as at the end of every ebb tide there remains some land water in the harbor. The amount remaining, which is the amount in excess of the run-off, is variable, due to the seasonal variations."

31 To obtain the amounts of sea and land water which return on succeeding tides, and which is, therefore, not available for dilution, but which may be considered as dead water, swinging back and forth, and which is ultimately displaced by the sewage requires float or current meter measurements to determine the average velocity of the tidal movement in each tidal cycle, the observations being made at some point of known cross section. Such

measurements were obviously impossible in the time available for the work of this Committee, and, therefore, the sea water available for dilution, to be added to the computed land water available for dilution, has been determined by taking the tidal prisms in the assumed tidal areas, affected in each harbor, as shown on the maps of Harbors, Pages 1 to 25.

At Washington and Savanah, the chlorine content in the harbor water was so low as to indicate that the total available dilution was due entirely to the fresh water flow.

At Baltimore, the change in the amount of chlorine in the upper end of the North West Harbor and in the Patapsco River, outside of this harbor, was so slight as to indicate that the fresh water flow was but a very small per cent of the total water available for dilution. Sufficient data were not at hand, however, to determine precisely the relative average salinity of the water in the upper end of the North West Harbor and in the Patapsco River outside of this Harbor for the purpose of cumputing the exact ratio of fresh water to sea water. Under these circumstances, the volume of the tidal prism comprised within the limits of the North West Harbor was taken as the total available water for dilution. As this harbor is a dead end harbor, the tidal prism probably gives a fair rational basis
32 of estimate, and probably a greater dilution than actually occurs. The resulting dilution of 1 to 26 falls where it should, when the conditions obtaining in Baltimore are compared with those of Havana on the one hand, and those of New York on the other. Moreover, Baltimore Harbor is so putrid that it has evidently passed considerably beyond the critical point, and even should the estimated dilution be somewhat high, there would be a big mârgin between the true dilution at which general nuisance will occur and the dilution as estimated for Baltimore.

Comparisons made in Jacksonville, between an estimate of the total available dilution based on the assumed tidal prism and one based on salinometer percentages, were found to accord closely.

At Havana, the same method was used as at Baltimore, with comparable results. At the other places, the dilutions were so great that a slight error in stating the total sea water available for dilution would not materially affect the results.

The results given, therefore, should give a fair expression of the actual conditions as to total dilution, and as the range of difference in the resulting dilution in the various harbors is so great, no serious inaccuracy in making general comparisons is introduced.

Some criticism may be made assuming the tidal area of New York as that of Upper New York Bay. This will make no practical difference in the final results. So long as the assumption of the amounts of new land and sea water available for dilution are even approximately accurate, the only effect of extending the tidal area considered so as to include the Hudson and East Rivers, Kill von Kull
33 and Newark Bay, will be to increase the stored water volume available for dilution. Below mean low water there is a fixed amount of water requisite to fill the depressions constituting, when filled with water, the various bays and rivers. This dead

water, or stored water, is continually replaced, or renewed, by tidal and land water flow. If, then, the tidal and land water flow were excluded and sewage in amount of that now emptying into the various tributaries to Upper New York Bay were allowed to enter into these basins, it would gradually replace all of the stored or dead water in those basins. If, then, the tidal and land flow were allowed to enter again, the dilution would result only from such flow. The only effect, therefore, of extending the tidal area is to increase the amount of stored water and to somewhat delay the date at which net dilution will obtain. As the process of emptying sewage into streams, rivers and bays tributary to Upper New York Bay is a continuous one, and has continued for many years past, it is safe to assume that the net dilution now effected is the ratio of the new sea and land water passing through the Bay to the sewage passing therethrough. The detailed explanation of the manner of determining these factors for New York is found on Page 30 of this report.

Standards of Purity.

In an attempt to establish some simple standard, limiting the amount of sewage which may be safely discharged into a stream, or tidal estuary, without producing putrefactive nuisance, an effort has been made to fix upon the minimum allowable dilution of the sewage which will result from discharging it into a body of water.

34 From observations made by Stearns, Hering and Goodnough, the proportion of sewage which can be safely discharged into a stream may be expressed as follows:

Nuisance Probable	1 in 16 to 1 in 23
Nuisance Improbable	1 " 36 " 1 " 45

Roughly speaking, then, a stream may be able to purify one-fiftieth of its volume of sewage, but not one-twentieth. These conclusions were drawn with relation to fresh water streams. Whether or not sea water will absorb more sewage than land water, without producing nuisance, has never been practically determined, but it is worthy of remembrance that sea water, when saturated with oxygen, contains about 20 per cent less oxygen than land water at like temperatures. From this fact alone it seems probable that, for like quantities, land water will dispose of more sewage than sea water.

However this may be, the data presented in Col. 6, Table 3, show clearly that with a dilution of 1 in 26, as in Baltimore, general nuisance will result. The "basin" at the upper end of the North West Harbor in Baltimore is little better than an open cess pool in which septic action is active and from which foul odors emanate. It is no exaggeration to say that the whole North West Harbor is in a state which makes it an injurious nuisance.

Havana furnishes another example of a like nature where the dilution is placed at 1 in 11.

Everyone is more or less familiar with the present conditions in New York Harbor, which are described in detail in several volum-

inous reports. It is sufficient to say that conditions here have not yet reached the acute stage. The results of our observations, therefore, indicate that with an available dilution of one in sixty,
35 a harbor will reasonably, though not perfectly, digest the sewage emptying into it, but will not do so with a dilution of one in twenty-six. This estimate accords reasonably well with Stearns, Hering and Goodnough, especially so, if the difference in the oxygen content of land and sea water is considered.

Estimates of the sewage tributary to Upper New York Bay in 1940 indicate that the dilution will be reduced at that time to 1 in 26 (Col. 6, Table No. 3) or the same as at present in Baltimore.

The general conclusion to be drawn from this statement is that the New York Harbor is fast approaching the limit of its capacity to digest sewage without resulting general nuisance.

Of course, it must be remembered that the use of dilution ratios as a means of fixing a standard for harbor pollution is, at best, misleading, insofar as it does not express in any way local nuisances which may result to the detriment, not only of property, but of health in the vicinity of sewer outlets. Dispersion and diffusion are so intimately associated with the results to be obtained from dilution that no specific statement of the effect of dilution can be made without knowledge of local conditions.

On the other hand, the amount of dilution does furnish an extended view of general conditions and is of assistance in pointing to general conclusions. It is useful so far, and no farther.

Dissolved Oxygen.

The percentage of saturation of dissolved oxygen in the water of various harbors, as shown in Column 7 of Table No. 3, in-
36 dicates that it follows, in a general way, inversely as the degree of pollution. In other words, the greater the pollution, the smaller the amount of dissolved oxygen. The figures given are interesting in fixing the probable limits to the amount of dissolved oxygen requisite in harbor waters.

Theoretically, while any dissolved oxygen remains in a water, there should be no putrefaction. As a matter of fact, it has been recognized by authorities at home and abroad that malodorous conditions due to putrefactive action may take place long before the oxygen content of a water has been completely exhausted. The degree of oxygen saturation requisite to prevent malodorous conditions varies with many factors, and opinions on the subject differ widely. At best, this method of gauging permissable pollution, when considered alone, is unsatisfactory, but it may be useful in conjunction with other standards in establishing broad lines of differentiation.

In Baltimore Harbor, with an average dissolved oxygen content of practically 23, marked evidences of putrefactive action were apparent all over the harbor, notwithstanding that the temperature of the water at the time of examination was about 46° F.

In Upper New York Bay, the percentage of saturation of dissolved oxygen is 67, and there are no general evidences of septic action,

such as exist in the North West Harbor at Baltimore. The results of these observations indicate that if the average percentage of saturation of dissolved oxygen in a harbor water falls somewhere between these limits, the nuisances resulting from putrefactive action will follow.

37 Local nuisances near the sewer outfalls may exist, however, in harbors where the average dissolved oxygen content is much higher than the figures just mentioned. At Jacksonville, where the lowest percentage of dissolved oxygen recorded was about 64 per cent, there was evidence of local putrefactive action in the vicinity of several of the sewer outfalls. The same conditions were noted at many other places.

Putrescibility of Harbor Mud.

Unfortunately, as shown in Column No. 8, Table No. 3, your Committee was able to obtain samples of the bottom mud from the harbors of but few of the cities visited. A comparison of the analyses of those samples collected, however, as well as of analyses of bottom mud from lakes and ponds of known purity, as shown in the Table giving the results of "Quantitive Putrescibility Tests on Mud", (Appendix No. 1, Page 69) shows that the degree of putrescibility of harbor muds corresponds generally with the degree of pollution. In Atares Bay, Havana Harbor, where the dilution was least and the dissolved oxygen was exhausted, the mud was putrescible when diluted in twenty-two hundred times its volume of distilled water, in Baltimore Harbor in eight hundred and thirty times its volume of distilled water, while the Massapequa Pond mud was only putrescible when diluted one to seven.

It is to be regretted that quantitive putrescibility tests on the mud of New York Harbor were not carried on by the Metropolitan Sewerage Commission, as such tests may serve as an additional index in fixing upon the permissable limits of the pollution of harbors. They are especially interesting in relation to the development of local nuisances. Every additional slant on this important question is useful, for, with the many varying factors and

38 changing conditions in every harbor, detailed data accumulate rapidly, and one's sense of perception is clouded in a mass of figures and correct conclusions are obscured unless simple tests and simple lines of study are adhered to. It is only upon broad general conclusions that the safe permissable degree of pollution of any harbor can be settled. The problem does not lend itself to refined scientific diagnosis. Broad comparisons along different lines are essential to a conclusion, and quantitive putrescibility tests on mud give a simple additional line of evidence.

Tons of Wet Sludge per Million Cubic Feet of Water Available for Dilution.

Column No. 10 of Table No. 3 gives the tons of wet sludge which will be produced by the estimated amount of sewage (Column No. 3) which will enter into the various harbors listed.

It is seen that the quantity of wet sludge varies in general inversely as the estimated total dilution (Column No. 6).

The amount of wet sludge produced, thus expressed, gives another simple way of gauging the permissable density of pollution, and entirely removes the factor of sewage strength, as the estimates of the quantity of wet sludge have all been reduced to a population basis. (See Appendix No. 3).

It is seen that 14-6/10 tons of wet sludge per million cubic feet of total water available for dilution are delivered into Atares Bay at Havana; 6 tons into the North West Harbor at Baltimore, and 3-4/10 tons into New York tidal waters, at the present time. Assuming that the population of the Metropolitan District of
39 New York will be 12,000,000 in 1940 (Table No. 2, Page 28), and estimating upon the same per capita contribution of wet sludge as produced in 1910, we find that there will be delivered into New York Harbor in 1940, 6-8/10 tons of wet sludge per million cubic feet of new water available for dilution. It is interesting to note that in 1940, the total dilution and tons of wet sludge per million cubic feet of water available for dilution in New York Harbor, will be approximately equal to the figures for the North West Harbor in Baltimore at the present date, where conditions, as has been previously stated, are obnoxious.

Value of Standards.

The difficulty of finding a simple rule, or fixed standard of purity, for use as a medium for the practical expression of the safe limit of pollution, without danger of passing the critical point, at which a harbor or tidal estuary, as a whole, will assume generally unsatisfactory condition, has been referred to in several paragraphs of this report.

Of the standards suggested in this report, the amount of dilution and the oxygen content of the water have been most generally used. A certain amount of dissolved oxygen is required to convert the organic matter in sewage into gases and mineral salts. This leaves the water for the time, deficient in the quantity of dissolved oxygen present. The amount of this deficiency is a measure of the activity of the processes of decomposition and of the capacity of the water to decompose additional organic matter. In the absence of dissolved oxygen, putrefaction takes place, accompanied by foul odors.
40 As has been stated, putrefaction should not occur, theoretically, as long as any dissolved oxygen remains, but, practically, it has been found that it does occur when an appreciable amount of oxygen is present in the water. Opinions differ widely as to the point below which the dissolved oxygen may be safely reduced. Some claim 70 per cent of saturation is necessary to prevent malodorous conditions, others 50 per cent, and some foreign authorities place the limit even lower.

Standards based on the permissable minimum dilution are necessarily founded upon numerous observations of the chemical con-

stituents found in waters, corresponding to such dilutions, on the assumption of a fair normal composition for water and sewage.

Standards of the permissable minimum dilution, as applied to the general conditions in a harbor, must be based on the assumption that sewage is emptied into a body of water of unvarying volume, flowing with sufficient rapidity to prevent deposits. If instead, the sewage is turned into a body of water where the currents are sluggish, the solid particles of the sewage may accumulate and decompose, giving off offensive gases. Fluctuations in tide, where they cause large areas to be alternately covered with water and left bare, as at Lynn, Mass., and large areas of shallow water are unfavorable for the proper disposal of sewage. Marshes are similarly unfit.

The extent of diffusion and dispersion of sewage must be considered in connection with a standard for the minimum permissable dilution, as the total dilution based upon the total flow in a harbor is never safe, for the reason that sewage emptying into a
41 harbor is never so diffused and dispersed as to include the total flow available for dilution, and then there is the deposition of solid matter at slack tide, causing the accumulation of mud on the harbor bottom and the inability of this mud, as the layers become thicker, to extract oxygen from the water at a sufficient rate to prevent putrefactive action. The form and depth of the sewer outlet, its location, the density of harbor water, as well as its temperature, to some extent its turbidity, and the tidal movement at the outlet must all be considered. Density, dispersion, diffusion, dilution and depth are each important modifying elements.

In short, there are many things which require careful consideration in each case, and many factors which cause a considerable variation from any general rule which may be laid down. The factors affecting standards based on the minimum permissable dilution affect equally as well as standards based on the dissolved oxygen content of harbor waters, or the other standards which have been proposed from time to time, such as the determination of free and albuminoid ammonia, of nitrates, putrescibility tests, and a combination of the tests for nitrates, or the ammonias, and dissolved oxygen.

Many authorities in England claim that no test or standard of any value has as yet been determined, and this view cannot be criticised insofar as there is certainly no general standard which suggests the local and specific nuisance which may occur as a result of emptying sewage into adjacent tidal waters, even though the general conditions are such as not to affect the human senses appreciably.

42 Your Committee have added the "Quantitive Putrescibility Tests on Harbor Muds," as they express more particularly the condition of the deposed suspended organic matter carried by the sewage and which usually cause the putrefactive odors.

It is not impossible to have a large theoretical dilution and a reasonably high oxygen content and yet encounter the putrefactive action of mud on a harbor bottom. When this action occurs, odors and consequent nuisance will be produced in greater or less amounts

depending upon local conditions, and it seems, therefore, that an important factor in the determination of the safe general limits of pollution in a harbor should take into consideration some standard relating to the permissable putrescibility of harbor mud.

It may be said, indeed, in nearly all cases, that at the outlets of outfall sewers, where the deposition of suspended matter is greatest, the olfactory nuisance frequently occasioned, arises more from the putrefaction of the mud than from the presence of sewage in the vicinity.

The last standard suggested in this report of the allowable tons of wet sludge, per million cubic feet of available water for dilution, is more definite than the simple method of expressing dilution as a ratio between the volume of sewage and the volume of water into which it discharges, for the reason that sewage strength varies with its per capita volume and the total amount of organic matter to be digested is really a function of the population served rather than of sewage volume.

Your Committee does not feel that the standards presented
43 are necessarily interpretable within close limits, but that, when considered together, they harmonize sufficiently to convey in a clear general way the critical point at which the general condition of a harbor will become offensive.

Form of Nuisance.

Various terms have been used to express an undesirable condition in a harbor or stream resulting from sewage pollution. It is customary to sum up the whole condition resulting from sewage pollution under the generic term of "Nuisance," and attempts have frequently been made to classify the different kinds of nuisances resulting from the presence of sewage in harbors.

The first classification which naturally suggests it-self is that of general and local, the general nuisance relating more specifically to those conditions which prevail in harbors which have been grossly polluted, and where the area affected by nuisance is co-extensive, or nearly so, with the harbor area, or at least with the area of a large section of the harbor.

Local nuisances refer more particularly to those, resulting in the vicinity of sewer outfalls, or those found in restricted or confined areas.

Nuisances also may be classified as "sensible," of which class there are two sub-divisions, namely, "visual" and "olfactory."

Another form of nuisance may be "injurious," and in this class may be included "infective" nuisances, or nuisances which produce sickness through infection resulting therefrom. Sensible nuisances, while not necessarily infectious, may produce injury to property, as, for instance, through the soiling of beaches, through the
44 injury to paint by the evolution of hydrogen sulphide, through the depreciation of property by the stench developed or by visual filth.

Definition of Nuisance.

It is no less difficult to phrase a definition expressing the condition which constitutes a nuisance than it has been shown to be to establish a simple rule or standard for determining the critical point at which a general nuisance will result.

The following definition, however, is offered as a reasonable one: A state, condition or thing which produces involuntary repugnance through the senses of a normal man, or which causes injury to the property or health of man.

It is not necessary for a nuisance to become general in order for it to conform to this definition, and yet it must be admitted that the definition is a reasonable one, as it applies more specifically to man's comfort than to his esthetic sense. It is uncomfortable for the normal man to live or work in a stench, or to be surrounded by visual filth. It is uncomfortable to be damaged in person or property. The use of a harbor in such a way as to transgress the just restrictions upon such use, which the proximity of other persons or property, in a civilized community, imposes upon what would otherwise be rightful freedom, is a nuisance. It is not necessary for the entire community to suffer discomfort; if only a fractional part does so, then just restrictions are transgressed. The number of people
45 affected has only to do with the extent of the nuisance, its quantitive and not its qualitive aspect.

Local Nuisance.

Long before a harbor has become a general nuisance, as in the case of the North West Harbor at Baltimore, local nuisance occurs as a result of sewage pollution.

An estimate of the extent and degree of the local nuisance resulting from sewage is dependent upon many factors, and it is necessary to deal with conditions as they have been observed to exist in order that such an estimate may be accurate.

Appearance of Sewage.

When an average sample of unscreened or unsettled sewage is placed in a bottle, the sewage has a dirty, gray color; if fresh, a musty and rather unpleasant odor, and if stale, a decidedly disagreeable odor, not unlike that of hydrogen sulphide. It contains the usual sewage filth, toilet paper, broken down feces, grease balls, trash, match sticks, etc. The particles of suspended matter vary materially in size. The small solid particles are usually composed of fecal matter, disintegrated paper, fiber and cloth, and ordinary detritus. When allowed to stand, much of the suspended matter settles down, causing a dirty, gray slimy sludge to accumulate at the bottom. If allowed to stand at summer temperature, the sewage becomes putrid. If greatly diluted, the sewage does not putrify, nor give off offensive odors, the decomposable organic substances being gradually
46 oxidized and converted into harmless and inoffensive compounds. The offensive odors of putrefaction are produced when the natural purifying agencies are overtaxed.

When crude sewage is emptied into a harbor it carries with it all of the suspended matter which is inherent in it, and the suspended matter and detritus in the sewage creates the visual nuisance.

When a sewage is discharged into a harbor where the turbidity is low, a marked discoloration of the water usually occurs and the water contains a large mass of visible particles of the paper, feces, and other solid matter, and the water of the harbor becomes decidedly turbid. The surface which is discolored is frequently sharply separated from the surrounding water, and as the current or tide carries the sewage away from the outfall, this discoloration expands.

As a rule, the sewage keeps its integrity well, but it eventually loses its turbidity by intermixture with the waters into which it is discharged.

The surface of this discolored area is usually covered with a film of grease. This greasy film is persistent and usually lasts longer than the discolored area with which it is first associated. Long after the turbidity has disappeared from the surface, particles of paper and suspended matter, and minute white flakes in large numbers may be observed. The white flakes consist largely of insoluble soap which have been produced by chemical combination between soluble soap and the calcium and magnesium salts, which are present in both salt and fresh water.

47 **Density.**

Sewage when discharged into sea water will rise to the surface, and this rise is due chiefly to the difference in specific gravity between the two liquids.

Turbidity.

Turbid waters act as a mask to shield visual effects. In Washington and Savannah, this was marked and no doubt the visual nuisance in waters with a turbidity of above fifty parts per million will be confined within very restricted limits.

Visual Sewage Field.

When sewage is emptied into a harbor at the surface, it spreads out over the surface water in the vicinity of the outlet, carrying with it the filth, the specific gravity of which is insufficient to cause immediate settlement.

If sewage is discharged horizontally below the surface of a harbor, the inflowing sewage preserves its integrity for a considerable distance, depending upon its initial velocity at the outlet, and rising upwards, spreads out in a layer upon the surface, and carrying with it, as before, the suspended filth which does not readily settle.

If directed upward vertically, the discharged sewage immediately rises to the top in a gradually enlarging column, forming a mushroom shaped cone at the surface, and spreading out thinly at the top upon the water surface.

If deflected downward at the outlet, the sewage spreads to some ex-

tent at the sewer opening, and, reversing its direction of flow,
48 rises upwards about the opening of the sewer and spreads out on the surface.

The rate at which the sewage will rise is a function of the relative density, or salinity, of the harbor water and of the sewage discharged. The greater the salinity of the water, the more rapid the rise. Temperature, also, plays some part in this phenomenon, and the greater the difference in temperature between the sewage and the water, the greater the rate at which the sewage rises to the top. The observations of your Committee, however, lead them to believe that the temperature effects are considerably less by comparison than those caused by differences in salinity.

The tides, or currents, in a harbor, passing the sewer outlet distort to a greater or lesser extent, depending upon the velocity of those tides or currents, the normal curves, or lines, which the rising sewage would follow in still water, and thus change in some small degree the location of the point at which the rising sewage stream intersects the surface of the harbor water. At ordinary depths, however, the deflection of the sewage as a result of tidal, or current velocities, is not sufficient to remove the visual effects produced on the water surface.

Observations of the sewer outfalls at Havana, Tampa, Jacksonville, Savannah, Charleston and Washington prove that the general statements, above made, with relation to the action of sewage thus discharged, are not affected materially by tides or currents. These outfalls included those discharging horizontally at the harbor
49 surface, horizontally below the surface, vertically below the surface, and downward below the surface, those placed below the surface varying in depth from nine to thirty feet below mean tide.

When the sewage reaches the surface it gradually spreads, actuated by the influence of surface currents, winds and tidal phenomena. The shape and form of the visual sewage field is materially affected by local conditions with respect to these elements, and no broad statement can be made. The location of the sewer outlet has a marked effect upon the form of the sewage field. For instance, if the outlet is adjacent to the shore, where the velocity of the current is retarded, the sewage field hugs closely to the shore and parallel to it, following the general direction of the current in mid stream, and forming a long, narrow parallelogram. If the outfall is carried nearer mid stream, the sewage field follows the direction of the current taking the form of a distorted trapezoid or trapezium, with its longest axis parallel to the direction of tidal or current flow, its form depending to a great extent upon the direction and velocity of the wind.

The sewage field is movable with the tides, currents and winds, swings up or down stream as the tide reverses, and spreads out or contracts under the influence of the wind.

As the sewage field spreads, diffusion takes place gradually, until, at some observable limit, varying in distance on divergent radii, from the outlet as a center, the visual field disappears. At this point

the visual nuisance ceases, but deposition of the suspended
50 matter may continue for great distances and under proper conditions this deposition may produce olfactory nuisance. Infective nuisance may continue beyond the limits of the olfactory nuisance produced by the putrefactive action of the bottom mud formed by the deposition of solids.

Diffusion and Dispersion.

The suspended matter contained in the sewage is carried from point to point by the tidal currents and by the action of the wind. Some of the solids may be carried several miles without losing their characteristics. The mixture, however, between sewage and harbor water goes on progressively, taking place from the outside edge of the discolored area. The greatest diffusion proceeds apparently from the bottom of the sewage mass.

The transporting power of water for suspended sewage solids varies as the square of the velocity of the moving current. Therefore, if the velocity is reduced by one-half, the capacity of the water to carry solid particles in suspension will be reduced to one-quarter. The effect of the velocity of current on transporting power is a very important element in the dispersion of sewage matter, for when harbor water becomes slack by reason of the change of tide, deposition goes on rapidly beneath the sewage field, piling up the sewage sludge on the bottom, there to lie and putrefy, and as the odors caused by the putrefaction of deposits upon the bottom are the most intense and offensive of any odors produced by the discharge of sewage into a harbor, the manner of dispersion and diffusion of the sewage plays an important part in the local nuisances produced.

51 Another factor in the dispersion of sewage, and one which should not be overlooked, is that the relative rate of deposition of solid matter in sea water is much greater than in fresh water. Water which is strongly saline will not transport as much solid matter in suspension as will water without salt. The capacity of a harbor, therefore, for carrying sewage matter to sea cannot be safely estimated from the information obtained merely from a study of inland rivers.

It may be said, in general, that deposits of sewage sludge exist not only in the immediate neighborhood of sewage outfalls, but to a degree, for considerable distances from these outfalls.

Local sewage discharge, therefore, may cause grave sensible nuisance, extending over large areas and in considering the problem of harbor pollution these local nuisances must be of prime consideration, even though a larger area of harbor may be unaffected by them. Standards for dilution, for the permissible per cent of oxygen saturation, or other standards, based on general averages, are no guide to the local nuisance which may result. A study of local physical conditions at sewage outfalls, as they exist, is essential to a conclusion.

51a

Chemical Studies.

In addition to the field determinations of dissolved oxygen, salinity, turbidity and the putrescibility of muds, special experiments were conducted by Mr. Leon R. Whitcomb, chemist in the laboratory of one of your Committee, Mr. Nicholas S. Hill, Jr., with relation to the comparative results obtained by the Winkler and Levy methods for the determination of dissolved oxygen, and also for the purpose of determining the effect of nitrites in the accuracy of the Winkler method.

The laboratory methods and apparatus used, together with detailed description of the work outlined above, is given in Appendix IV.

The results which are shown in the Tables Appendix IV have been corroborated by independent investigations conducted by Dr. Jackson at the Mount Prospect Laboratory.

51b

Summary and Conclusions.

1. A general nuisance will, under ordinary conditions, result in a harbor into which sewage is emptied:

a. When the dilution approaches 1-26.

b. When the per cent of saturation with dissolved oxygen falls to 23.5.

c. When the number of tons of wet sludge per million cubic feet of total new water, available for dilution, amounts to 6.

2. A general nuisance may occur in a harbor into which sewage is emptied:

a. When the ratio of dilution falls at some point between 1-60 and 1-30.

b. When the per cent of saturation with dissolved oxygen falls at some point between 65 and 23.5.

c. When the number of tons of wet sludge per million cubic feet of total new water, available for dilution, amounts to between 3.5 and 6.

3. A general nuisance will not occur in a harbor into which sewage is emptied under ordinary conditions:

a. When the ratio of dilution exceeds 1-60.

b. When the per cent of saturation with dissolved oxygen exceeds 65.

c. When the number of tons of wet sludge per million cubic feet of total new water, available for dilution, is less than 3.5.

4. No standards or rules relating to general conditions give a basis upon which an estimate can be made of the extent to which local nuisances may occur.

5. Serious local nuisances, sensible, injurious and infectious, frequently occur where there is no general nuisance.

51c 6. The present pollution of New York Harbor is approaching the critical point at which a general nuisance may occur.

7. If the crude sewage from the Metropolitan Sewerage District, or a large part of it, continues to be discharged into the tidal waters

in the vicinity of New York, up to 1940, serious general nuisance will probably result at, or before, that time.

8. Serious local nuisances now exist in New York Harbor.

9. It seems from comparative experiments conducted with the Levy and Winkler methods for the determination of dissolved oxygen, that the true percentage of dissolved oxygen presented in this report, and as stated for New York Harbor by the Metropolitan Sewerage Commission and the Central Committee Experts, is, if anything, rather higher than the true percentages which actually obtain.

10. To discharge crude sewage from the Passaic Valley Sewerage District, in the amounts proposed, and at the point selected at Robbins Reef, would create another local nuisance of wide extent and materially hasten the approach to the critical point at which a general nuisance will exist in Upper New York Bay.

Respectfully submitted,

DANIEL D. JACKSON.
THEODORE HORTON.
NICHOLAS S. HILL, Jr.

March 15, 1912.

52 APPENDIX I.

Giving Basic Data and Explanation of the Method of Obtaining Land-water Drainage Areas Tributary to the Harbors Considered, the Annual Rainfall in These Drainage Areas, the Volume of Land Water Flow, the Tidal Ranges and Tidal Areas of the Harbors Considered, and the Normal Characteristics of the Harbor Waters (Table No. 1, Page 28).

A. The Tributary Land Water Drainage Area, Col. 2, in the case of each harbor, has been carefully computed from the best obtainable maps.

For Havana, no reliable map was obtainable, and the statement of Mr. H. E. Hyde of the Obras Publicas, Havana, has been accepted.

For New York, the area is given as stated on Page 14 of the Central Committee's "Basic Physical Data Relating to the Metropolitan and Passaic Valley Sewerage Districts.

For Baltimore and Boston, it was computed from the topographical maps of the United States Geological Survey.

For Washington, the drainage area of the Potomac River is taken as stated in a paper on "Hydrography of the Potomac Basin," Trans. Am. Soc. C. E., Vol. XXVII, Page 21 et seq.

For Savannah, the drainage area of the Savannah River above Augusta was obtained from Water Supply and Irrigation Paper No. 204. Below Augusta, and above Savannah, it was computed from a State map of Georgia, published by the Georgia State Geo-
53 logical Survey, and the total area thus derived was checked with local estimates.

For Tampa, Jacksonville and Charleston, it has been taken from the United States Post Route maps.

B. The Mean Annual Rainfall, Col. 3.

For Havana, was estimated from data relating to the State of Florida, obtained from the United States Weather Bureau.

For Baltimore, the value used is that given by the records of the Baltimore City Water Department.

For Washington, the mean annual rainfall for the Potomac Basin was obtained from the paper on Rainfall and Stream Flow by John C. Hoyt, Trans. Am. Soc. C. E.; Vol. LIX, Page 455.

For Savannah, the figures given in the Table, Page 54, of the rainfall in the Savannah River Basin were used. The rainfall figures used in this table, as well as in the tables for the Ocmulgee, Oconee, Broad, Cape Fear and Roanoke Rivers were obtained from published reports of the United States Weather Bureau and were carefully compiled.

For Tampa, Jacksonville and Charleston, values have been obtained from a careful study of the data on rainfall in the basins of comparable southern rivers shown in the tables, Pages 54 to 57.

For Boston, the figures for the Sudbury River shown in the Table, Page 58, are used, these figures having been carefully compiled from the records of the "Boston Metropolitan Water and Sewerage Board," published in their reports.

(Here follow tables marked A, B, C, D, and E, pages 54, 55, 56, 57 and 58.)

59 C. The Fresh Water Flow, Col. 5, or Total Available Run-off.

At Havana, was estimated from the best data available, and taken at one (1) second foot per square mile.

At Baltimore, in estimating the total run-off available from the basin of Jones Falls, an area sufficient to supply the quantity of water taken from the stream, for water supply purposes, has been deducted from the total area of the basin, and the resulting quantity of run off has been checked against the records of the Baltimore City Water Department of the flow of Jones Falls, from which the City obtains a portion of its water supply.

At Washington, the volume of run off has been computed from the data presented in the paper on "Hydrology of the Potomac Basin, Trans. Am. Soc. C. E. Vol. XXVII, Page 21 et seq., and checked against gaugings of the Potomac River reported by the Superintendent of Sewers, Washington, D. C., in his report for the year 1910.

At Tampa, Charleston and Jacksonville, the run-off has been estimated by assuming 40 per cent of the rainfall as available run-off, 40 per cent being estimated from a careful study of the comparable southern rivers, data for which *is* shown in the tables, Pages 54-57.

At Savannah, the runoff was computed from the data shown in the Table, Page 54, which has been carefully compiled from gaugings of the Savannah River reported in the publications of the United States Geological Survey.

60 At Boston, the run-off was computed from data for the Sudbury River shown in the table, Page 58, which has been carefully compiled from the published records of gaugings made by the Boston Metropolitan Water and Sewerage Board.

D. The Tidal Range, Col. 6.

In Upper New York Bay was obtained from the "Report of the New York Metropolitan Sewerage Commission, 1910," Page 156.

For Boston, from the statement of the Boston Metropolitan Water and Sewerage Board.

For Charleston, from the office of the Charleston City Engineer, and

For the other harbors from local sources, and checked against the tidal range given on the United States Coast and Geodetic Survey Charts of the harbors in question.

E. The Tidal Area Considered, Col. 7.

For New York is the area of Upper New York Bay as stated on Page 156 of the "Report of the Metropolitan Sewerage Commission of New York, 1910."

For Boston, the tidal area is used as stated on Page 147 of Appendix XIX of the "Report on Sewage Disposal of Paterson, N. J." by Allen Hazen.

For the other harbors the tidal area has been computed from the harbor charts of the United States Coast and Geodetic Survey.

F. The Physical and Chemical Characteristics of the Harbor Waters, Cols. 8, 9, 10 and 11, have been taken from the Tables Pages

(Ref. - W. A. Jones)

62-69, which show the results of analysis of samples of the
61 harbor waters made by D. D. Jackson and collected by your Committee, care having been taken in this case to select results which represent the normal harbor water, or water from those parts least affected by sewage pollution.

At New York, the chemical data were obtained from the report of the Metropolitan Sewerage Commission 1910, except the putrescibility tests on mud, which were made in the laboratory of Mr. Nicholas S. Hill, Jr., upon samples collected from New York Harbor on February 8, 1912, and February 13, 1912.

(Here follow tables marked F, G, H, I, J, K, L, and M, pages 62, 63, 64, 65, 66, 67, 68, and 69.)

70 APPENDIX II.

Giving Basic Data and Explanation of the Method of Determining Total Population, Tributary Population, Domestic Sewage Flow, Manufacturing Wastes, Ground Water Infiltration, and Total Sewage Flow.

Table No. 2, Facing Page 29.

A. The Population Figures, Col. 2, have been obtained as follows:
For Havana, from the statement of Mr. H. E. Hyde of the Obras Publicas, Havana.
For Baltimore, from the United States Census of 1910.
For New York, from figures given on Page 13 of "Basic Physical Data Relating to the Metropolitan and Passaic Valley Sewerage Districts," as follows:

	1910.	1940.
Total Population in Metropolitan District..	6,424,530	12,846,560
From this total is to be subtracted:		
1st. The population tributary to Long Island Sound	33,648	81,000
2nd. The population tributary to Lower New York Bay	345,403	966,000
3rd. 16 per cent of the population tributary to the Passaic, Hackensack and Newark Bay—this proportion of the sewage in Newark Bay has been estimated by the Central Committee as flowing into the Lower Bay, through the Arthur Kill, 16%	31,300	78,438
Total Deductions	410,351	1,125,438
	6,014,179	11,721,122

71 The following Table No. 4 shows that the estimate of a population of 12 million within the Metropolitan District in 1940 is very conservative.

TABLE NO. 4.

Comparison of Population Estimated, City of New York.

	1900.	1910.	1940.
*John R. Freeman.....	3,437,202	4,766,883	7,652,000
*Metropolitan Sewerage Commission	.....	.....	8,666,100
Central Committee of Experts State of N. Y.....	.....	.....	9,000,000
*N. Y. Telephone Co.	.....	.....	8,747,000
*Board of Water Supply ..	.....	.....	9,258,000
*Public Service Commission	.....	.....	13,700,000

For Washington, from the statement of Mr. Sawtielle of the Board of Health, Washington.

For Tampa, Savannah, Jacksonville and Charleston, from the statement of local engineers checked against the figures of the United States Census of 1910.

For Boston, as follows, from figures published in the report of the Boston Metropolitan Water & Sewerage Board 1910.

TABLE NO. 5.

	Contributing.	Total.
N. Metropolitan District	465,000	524,000
S. " "	230,000	360,000
Boston Main Drainage District	470,000	**487,000
	1,165,000	1,371,000

B. The Population Contributing Sewage. Col. 3, has been estimated as follows:

For Havana from the statement of Mr. H. E. Hyde, of the Obras Publicas, Havana.

* All estimates marked thus made before 1910 census were available.

** Deducting 183,000 population of Boston tributary to the Metropolitan Sewer System, from the 1910 Census population of Boston. (670,000—183,00 = 487,000).

72 For New York, by assuming 80 per cent of the total population to be connected to sewers.

For Baltimore, as follows:

Total area of the city.....		19,200	acres
Area of the densely built up portion of the city, 50%, or.....		9,600	"
Population	558,000		
	558,000		
Density	$\frac{558,000}{9600}$ =	58	per acre
Area tributary to North West Harbor		5,000	acres
Population in this area 5000x58..	= 290,000		
50% assumed connected to sewers 290,000 x 50%	= 145,000		population contributing sewage.

For Washington, by assuming 90 per cent of the total population to be tributary to sewers connected with the main sewage outfall.

For Boston, see Table No. 5, Page 71.

For Savannah, estimate of Mr. John W. Howard, City Engineer of Savannah.

For Jacksonville, estimate of Mr. R. N. Ellis, Supt. Water Electric Light and Sewers, Jacksonville.

For Charleston, Dr. J. M. Green, Health Officer, Mr. Dunlop of City Engineer's office and Mr. J. M. Diven, Supt. of the Water Company. The total number of houses is approximately 9,000, of which 6,000 have privy vaults or dry closets. There are probably 3,000 houses connected to the sewers and the total population, $59,000 \times \frac{3000}{9000} = 19,700$ population contributing sewage.

(Here follows table marked Exhibit N, page 73.)

(Exhibit N 1.75)

- TABLE No. 6. -
GROSS AND PER CAPITA CONSUMPTION OF WATER AT VARIOUS PLACES WITHIN THE METROPOLITAN DISTRICT OF NEW YORK.

Place	Per Capita Consumption (Gals. Daily)	Population	Total Consumption (Million Gals. Daily)
(1)	(2)	(3)	(4) = (2) × (3)
Greater New York	114.0	4,766,883	545.0

Exhibit O.--(178)

Data on The Infiltration of Ground Water into Sewers.

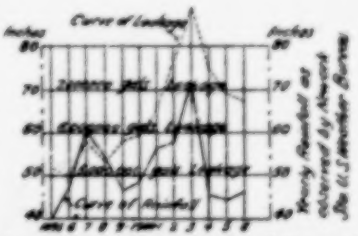

Diagram showing relation between rainfall and leakage into municipal sewage works as computed from records of flow of Union Outlet sewer from Orange, Montclair, Glen Ridge, and Bloomfield, N. J.

Passaic Valley Sewerage Comm. Report of Dec. 1907, page 11.

Table Showing Probable Leakage of Ground Water into Sewers of Orange, Montclair, Bloomfield & Glen Ridge from 1895 to 1906.

Date	Probable Leakage in Mill. Gals. / Day	Probable Leakage Gals. / Capita per day	Rainfall Inches per Year.
1895	52	87	49.83
96	50	84	46.68
97	582	97	60.69
98	537	88	54.17
99	5.04	97	45.68
1900	589	98	48.80
01	648	108	55.84
02	758	126	56.79
03	900	150	70.90
04	748	125	44.80
05	691	115	43.72
06	670	112	45.63
Ave.	643	107	51.14

Assumed population of 60,000, based on proportional population connected to sewers is the same (60%) in 1910 as in 1906.

Table taken from Passaic Valley Sewerage Commission report of December 1907. Page 13.

Data on Infiltration of Ground Water into Sewers

	Place	Size of Sewer	Length of Sewer Tributary to Section	Percentage of Sewage to Ground Water	Average Daily Flow of Sewage in Gallons	Average Rate of Infiltration per Inch Diameter per Mile per Day	Total Drainage in gals. per day	Remarks
1	Boston, Mass.	6'-10"	157		96000	50	5490000	Before any connect. to sewer.

(Schedule B - 9 of 9)

74 For Tampa, from the estimate of Mr. F. F. Warner, City Engineer of Tampa.

C. The Daily per Capita Volume of Domestic Sewage, Col. 5, is estimated as follows:

For Havana, it is assumed to be equal to the daily per capita consumption of water, as stated by Mr. H. E. Hyde of the Obras Publicas, Havana.

For Baltimore, it is assumed to be equal to the daily per capita consumption of water as shown in the records of the Baltimore City Water Department.

For New York, Table No. 6, opposite, shows the daily per capita consumption of water in various communities within the Metropolitan Sewerage District. The average daily per capita consumption of water is shown by this table to be 112.5 gallons; 113 gallons per capita daily has been assumed to be the volume of domestic sewage to be expected within the district.

It is a recognized fact that the per capita consumption of water increases as the total population increases, and a daily sewage flow of 130 gallons per capita has been estimated for the New York Metropolitan District in 1940.

For Tampa, 125 gallons per capita daily is assumed as a conservative estimate of the sewage discharged by a city of the size and character of Tampa.

For Savannah, Jacksonville and Charleston, the volume of sewage per capita daily is assumed to equal the daily per capita consumption of water which has been computed from data supplied by Mr. John W. Howard in Savannah, Mr. R. N. Ellis in Jacksonville, and Mr. J. M. Diven, Supt. of the Charleston Light and Water Company.

75 For Washington and Boston, the method of determining the amount of domestic sewage is included in the explanation of the total volume shown in Col. 8.

D. The Volume of Manufacturing Waste Derived from Private Water Supplies, Col. 6, has been estimated from careful consideration of the manufacturing and water supply conditions in the several cities.

E. Infiltration of Ground Water, Col. 7.

The curve and tables following Pages 76-77, show that ground water may leak into a sewer in quantities ranging from 2 to 442 gallons per day per capita of population served by the sewer. From a careful study of the tables, 50 gallons per capita daily has been assumed to be a fair average value.

In the case of Washington and Boston no infiltration is shown, as it is included in the volume of sewage shown in Col. 8.

(Here follow tables marked Exhibits O and P, pages 76 and 77.)

78 F. The Total per Capita Daily Volume of Sewage, Col. 8.

For Washington, the volume of 218 gallons per capita daily has been computed from the records of sanitary sewage and storm water pumped to the main sewer outlet during the year 1910-1911. See "Report of the Operations of the Engineer Department of the District of Columbia, for the fiscal year ending June 30, 1911," page 156.

For Boston, the volume was estimated as follows from data presented in the eport of the Metropolitan Water and Sewerage Board for 1910."

Sewer System.	Outlet.	Flow in gallons daily.
North Metropolitan,	Deer Island	60,000,000
South "	Nut or Peddock's Island	40,000,000
*B. M. Drainage	Moon Island	105,000,000
		205,000,000

* Mr. X. H. Goodnough, on Page 416 of the Report of the Mass. State Board of Health, 1905, states the discharge from Moon Island to be 100,000,000 gallons daily in 1905. Increasing this volume in proportion to the increased population, it becomes 105,000,000 gallons in 1910. In 1905 the population contributing sewage to the Boston Main Drainage System, having its outlet at Moon Island, was, 615,000—156,000 = 459,000. (See Report of Metropolitan Water and Sewerage Board, 1905, Page 144.) 100,000,000 ÷ 459,000 = 223 gallons per capita. 223 x 470,000 = 105,000,000. (See Table 25, Page 71).

80 APPENDIX III.

Basic Data for Estimating Tons of Wet Sludge per Million Cubic Feet of Sewage.

Table No. 7 gives the estimated total suspended matter in various sewages. The average of the six largest cities given in Col. 4 is 50 tons per 1,000 population per annum, which is the figure used in the report.

Table No. 8 gives the ratio of total dry solids to suspended matter in various sewages. The average ratio of the four largest cities is 3.38.

Table No. 9 gives the ratio of wet sludge to total dry solids, the average being 8.32.

We have assumed, therefore, 50 tons of suspended matter per 1,000 population per annum $\times$ 3.38 $\times$ 8.32 = 50 $\times$ 28.12 = 1,406 tons of wet sludge per 1,000 population per annum. Assumed population for New York—6,000,000 gross tons sewage sludge in 1911 = 6,000 $\times$ 1,406 = 8,436,000 tons, or approximately 9,540,000 cubic yards.

(Here follow tables marked Exhibits R and S, pages 81 and 82.)

83 APPENDIX No. IV.

Laboratory Methods and Experiments.

Although the methods employed by your committee in the examination of the water and muds from the various harbors considered are all well known and in general use, it is deemed advisable to give a brief description of them, together with a description of one or two studies made during the investigation.

The usual examination consisted of the determination of the temperature, dissolved oxygen, salinity and turbidity of the water and degree of putrescibility of the mud. A study was made to determine the relative value of different methods for the determination of dissolved oxygen, and a series of tests was made to determine the effect of varying quantities of nitrites on the accuracy of the "Winkler" method for the determination of dissolved oxygen.

Dissolved Oxygen.

The amounts of dissolved oxygen in the waters of New York Harbor have been taken from the figures presented by the Metropolitan Sewage Commission and given in their report. The method employed by that commission for the determination of dissolved oxygen was the "Levy" method.

The samples of water examined from harbors other than at New York were collected with the apparatus carried by your committee, and the quantity of dissolved oxygen was determined by both the "Levy" and the "Winkler" methods. These methods are described in detail at another point in this appendix. The results of these examinations showing the oxygen dissolved in the various harbor waters are given in the tables on pages 62 to 68.

84 Salinity.

The salinity of the various harbor waters examined was ascertained by the determination of the amount of chlorine present in the water. The chlorine was determined according to standard methods by titration with a solution of silver nitrate (2.4 grams per liter) using potassium chromate as an indicator.

Turbidity.

The turbidity of the water in the various harbors examined was determined by use of the United States Standard Turbidity Rod. In some few instances when no rod was available the turbidity was taken with a rule graduated in inches, and the reading calculated to parts per million by aid of the standard table. The turbidities at various points in the different harbors are shown on the tables pages 62-68.

Putrescibility of Muds.

The method used in determining the putrescibility of the mud from the bottom of the various harbors is that devised by one of this committee (D. D. Jackson) and W. A. Horton and published in the Journal of Industrial & Engineering Chemistry, June 1909 and which depends upon the decoloration of an organic dye by putrescible substances in the absence of available oxygen. The method as used is as follows:

Solutions of mud in various proportions are made by adding a definite weight of the wet mud to varying quantities of distilled water saturated with air at the room temperature (about 20° C.). One c. c. of methylene green (½ gram per liter) is added to each liter of the various dilutions. An eight ounce bottle is filled with the dyed solution of mud and a rubber stopper fitted with a short tube and rubber bulb, also filled with the mud solution, is
85 inserted in such a way that no air bubbles are enclosed. The water in the rubber bulb is then forced out, leaving the bulb collapsed. The bottle is now placed in the 37° incubator and allowed to remain at that temperature for four days. As fast as the solution in the bottle expands, because of the increase in temperature, the increase fills the rubber bulb. In this manner no solution escapes and no air is brought in contact with the solution after the test begins.

As soon as the oxygen dissolved in the solution is consumed by the organic matter in the mud, the dye present is attacked and the color disappears. This disappearance of color therefore indicates a putrescible condition and a higher dilution must be examined.

A sample of the wet mud is dried at 100° C. for one hour and the percentage of moisture determined. From this the actual weight of dry mud used may be determined and the correct degree of putrescibility may be figured.

The samples taken in New York Harbor were collected with a piece of apparatus shaped like a mushroom anchor weighing about ten (10) pounds and having a head twelve (12″) inches in diameter and six (6″) inches deep. The mud was obtained by dragging this anchor on the bottom of the harbor for a few feet and then bringing it to the surface. The results of these tests are given in the table on page 69, of Appendix I.

A Comparison of Various Methods for the Determination of Dissolved Oxygen in Sea Water.

Considerable discussion has arisen recently concerning the relative accuracy of various methods for the determination of dissolved oxygen in sea water. In order to convince ourselves on this
86 point, studies were made comparing the various methods.

Apparatus.—The apparatus used in the collection of samples of water from New York Harbor consisted of a container holding three separatory funnels of about 300 c. c. capacity and having

a small bulb in the stem and a two liter bottle. The container was weighted so that it would sink readily. The funnels and large bottle were so connected that the water was taken from a common point and passed through the funnels into the bottle. When the large bottle was filled the water in the small funnels had been changed several times thus securing a uniform sample free from contact with the air.

As soon as the container was brought to the surface the filling tubes were removed and stoppers inserted in the funnels, care being taken that no air should remain in the funnel. The tests were made as soon as the samples reached the laboratory which was not more than ten minutes from the time they were taken.

One funnel was used in making a test by the "Winkler" method and the other two were used in making a test by either the "Levy" or "Letts-Adeney" methods.

The methods used in making the determination of oxygen dissolved in sea water are known as the "Winkler" method, the "Levy" method and a third method referred to as the "Letts-Adeney" method and described in the Fifth Annual Report of the Royal Sewage Commission, Appendix 6, Pages 221-224.

Briefly described the methods are as follows:

Winkler Method.—The stopper is removed from one of the full separatory funnels and two c. c. of manganeous sulfate solution (48 grams to 100 c. c. of water) and two c. c. of sodium hydrate and potassium iodide solution (360 grams of hydrate and 100 grams of iodide to 1000 c. c. of water) are delivered at the bottom of
87 the funnel. The stopper is again inserted and the solutions thoroughly mixed. After standing for five minutes in the inverted funnel, four (4) c. c. of sulfuric acid (1:1) are admitted to the funnel through the stem. The acid dissolves the precipitate formed. The contents of the funnel plus the liquid replaced by the acid is rinsed into a half liter bottle and titrated with $\frac{N}{40}$ solution of sodium thiosulfate using five (5) c. c. of starch solution near the end of the titration as an indicator.

The calculation of the results is made from the formula as given on page 76 of the Report of the Committee on Standard Methods. Oxygen in parts per million $= \frac{200\ N}{V}$ where "V" is the capacity of the funnel, in c. c., less the volume of manganeous sulfate and potassium iodide solution added (less four c. c.). "N" is the number of c. c. $\frac{N}{40}$ sodium thiosulfate solution used in the titration.

Levy Method.—Six (6) c. c. of ferrous sulfate solution (48 grams of salt and five (5) c. c. of sulfuric acid per liter) and four (4) c. c. of sodium carbonate solution (200 grams per liter) are introduced at the bottom of the separatory funnel. The stopper is inserted and

the contents of the funnel thoroughly mixed. The funnel is then inverted and allowed to stand for five minutes. Ten (10) c. c. of sulfuric acid (1:1) are then admitted to the funnel through the stem. As soon as the precipitate is dissolved and the solution is colorless, the contents of the funnel are rinsed into a half liter bottle and titrated with standard potassium permanganate solution, made by dissolving 5.638 grams of salt in 1000 c. c. of water. One (1) c. c. of this solution is equivalent to one (1) c. c. of oxygen under normal conditions of temperature and pressure.

88 A blank test to determine the value of the ferrous sulfate solution is made by repeating this method with another funnel, but adding the sulfuric acid before the ferrous sulfate or sodium carbonate.

The result is calculated by subtracting the number of cubic centimeters of potassium permanganate required in the titration of the sample, from that required by the blank. This number divided by the volume of the funnel and multiplied by 1000 equals the number of c. c. of oxygen per liter of water and this multiplied by 1.434 equals parts per million.

Letts-Adeney Method.—Seven (7) c. c. of the sample are removed from the separatory funnel and five (5) c. c. of ferrous sulfate solution (48 grams per liter) are introduced at the bottom of the funnel. Strong ammonia is added until the funnel is full and the stopper is replaced, care being taken that no bubble of air is enclosed. The liquids being of different specific gravities the ferrous sulfate solution remains at the bottom of the funnel and the ammonia is at the top. When the funnel is agitated the liquids mix and a precipitate is formed. The funnel is inverted and allowed to stand for five minutes. Ten (10) c. c. of sulfuric acid (1:1) are then applied through the stem and when the precipitate has dissolved the whole is rinsed into a half liter bottle and titrated with standard potassium bichromate solution made by dissolving 8.7906 grams of salt in one (1) liter of water. Each c. c. of this solution is equivalent to one cubic centimeter of oxygen at normal temperature and pressure. The titration is made using potassium ferricyanide as an indicator.

(Here follow tables marked Exhibits T and U, pages 89 and 90.)

91 A blank test is made using a separatory funnel in the same manner as above but adding the sulfuric acid before the ferrous sulfate ammonia.

The result is calculated to parts per million by the same method as that used in the "Levy" method.

Comparison of Results.

Twenty-four (24) tests were made in the study to determine the relative accuracy of the various methods for the determination of dissolved oxygen. Eighteen (18) were made comparing the "Winkler" and "Levy" methods and six (6) comparing the "Winkler" with the "Letts-Adeney" method. The results expressed in parts per million and in per cent saturation together with the temperature, condition of tide, and amount of nitrite and chlorine present are recorded in the accompanying table.

The water used in these tests was taken from the East River at the outer end of Pier 15. This sampling point was chosen in view of the fact that a large sewer empties into the river under this pier, and the water at this point would therefore contain a high amount of organic matter.

It will be noted from the table of results that with the exception of two tests the "Levy" method yields higher results than does the "Winkler." Sometimes the "Levy" method produces a result so high as to indicate super-saturation. This seems highly improbable even at the low temperature, when the high amount of organic matter known to be present is taken into account.

92 The average difference in the per cent saturation between the two methods is 12.42%. The average difference expressed in parts per million is 1.59.

The effect of slight variations in the titration by either method may best be shown in the form of a table as follows:

Method.	Volume of reagent used.	Equivalent to parts per M.	% saturation at 0°C 15.300 parts per M., of chlorine.	Difference in % saturation, due to 0.1 c.c.
Winkler	14.1	10.01	80.59	0.56%
	14.0	9.94	80.03	
Levy	2.2	11.22	90.35	4.12%
	2.1	10.71	86.23	

It also appears that one (1) part per million corresponds to a difference of 8.23% in percentage of saturation with the conditions of temperature and salinity under which these tests were made. With higher temperature conditions the difference would be even greater.

The difference between the results obtained with the Winkler and Letts-Adeney methods are greater than the difference between the Winkler and Levy methods. Difficulty was also encountered in obtaining a satisfactory end point in several tests so that it was concluded that nothing was gained by using this method.

EFFECT OF NITRITES

Chlorine present = 13,200

Sea Water saturated with oxygen at 19°C
Containing 8.6 parts, Million.

The results and conclusions of the Central Committee are based on determinations made by the Levy method. It would seem from our experiments, made with these methods, that the true percentage of dissolved oxygen may be lower than that deduced by the Metropolitan Sewerage Commission from determinations by the Levy method.

(Here follows table marked Exhibit V, page 93.)

94 *The Effect of Nitrites on the Accuracy of the Winkler Method for the Determination of Dissolved Oxygen.*

Several investigators have stated that the accuracy of the Winkler method for determination of dissolved oxygen was impaired when nitrites were present. In order to determine the extent of the effect of nitrites on this method, a series of tests was made, using distilled water charged with oxygen, and salt water as taken from New York Harbor.

This salt water as collected contained 13,200 parts per million of chlorine and .015 parts per million of nitrites. It also contained 7.47 parts per million of dissolved oxygen. Standard solutions of potassium nitrite were prepared of such strengths that one (1) c. c. diluted to one hundred (100) c. c. increased the nitrite present by 1.000, 0.100, 0.010 or 0.001 parts per million. Since the salt water used in the tests had .015 parts per million of nitrites ordinarily present, it was impossible to determine whether this initial amount was sufficient to effect the determination of dissolved oxygen. In order to settle this question, distilled water free from nitrites and aerated until it was practically saturated with oxygen, was used for a second series of determinations.

The results of these tests are given in tabulated form in the table on page 93. It will be seen from this table that nitrites present in quantities of less than 0.500 have no effect on the determination of dissolved oxygen by the Winkler method. Since this quantity of nitrites is very rarely, or never present in waters to be examined for dissolved oxygen it appears from the studies here described that the Winkler method may generally be used without regard for the composition of the water.

Shellfish Investigation in Raritan Bay by New York State Department of Health.

JAMES D. MAHER,
Commissioner.

833 COMPLAINANT'S EXHIBIT No. 182. James D. Maher, Commissioner.

Sanitary Inspection of Shellfish Grounds.

One of the most important investigations carried on during 1908 and the one requiring the greatest amount of time and attention from the Engineering Division was an examination into the sewage pollution of those waters of the State in which shellfish are grown and matured.

This work, undertaken in accordance with the provisions of section 214 of the Forest, Fish and Game Law, was begun in the latter part of June, 1908, and occupied the time of one engineer and two special inspectors of the division for the greater part of the months of July, August and September. This investigation was made in co-operation with the hygienic laboratory and the work performed by the Engineering Division comprised detailed inspection and the collection of necessary data showing the extent and character of pollution discharged into the streams, bays and sounds of Long Island, comprising some 400 miles of shore line, together with such detailed inspection along the southeasterly shore of Staten Island. In addition to these statistics the location of leased oyster beds was procured from the Department of Marine Fisheries of the Forest, Fish and Game Commission, from the local authorities of various towns along the shores and from the county of Suffolk.

From the information thus collected a set of maps has been prepared showing by an appropriate index pollution data reported by the inspectors together with the location of leased oyster beds. On these maps appear, also, the position and number of the sampling stations from which samples for analysis of both water and oysters were procured and made by the laboratory division.

The results of the investigation have been summarized and described in the following report submitted in accordance with the provisions of the special act to the State Superintendent of Marine Fisheries:

834 ALBANY, N. Y., February 11, 1909.

Hon. B. Frank Wood, Superintendent of Marine Fisheries, Department Forest, Fish and Game, 1 Madison Avenue, New York, N. Y.

DEAR SIR: Section 214 of the Forest, Fish and Game Law requires that reports of the results of inspections of shellfish beds and shellfish made by inspectors of this Department, in obedience to sections 214 and 215 of the same law, shall be submitted to you "immediately."

The person or persons responsible for the drafting of these provisions were possibly under the impression that mere inspection of shellfish beds and the surroundings of the shellfish thereon would give sufficient evidence upon which an opinion as to their sanitary quality, that is fitness for food, could be expressed.

It is unfortunate, but nevertheless true, that such an inspection

as apparently was considered all that would be necessary would be of practically no value in giving results which could be relied upon for the determinations in question.

Only the most exhaustive study of the sanitary conditions of the waters, which might from time to time be over the shellfish beds, and the thorough investigation of all the possible sources of pollution of such waters, together with the determination of all the periodic and special conditions of tides, currents, variations of level, etc., added to and interpreted in the light of the findings of laboratory analyses and examinations of these waters and of the shellfish from these beds, would give any results upon which a satisfactory and fair determination as to sanitary conditions of the shellfish might be based.

Moreover, there is a further difficulty inherent in the State of our scientific knowledge regarding the relation of oysters to the transmission of water-borne diseases, especially typhoid fever. This is that no scientific or administrative body of all those who have made investigations in this direction, even over long periods and with ample scientific assistance, has as yet determined to its satisfaction any definite relation between any estimated pollution of water or of shellfish and the disease-producing liability of the pollution in such water or shellfish.

835 These difficulties, however, did not lessen the efforts put forth by this Department on this work during the last few months, but they have been conducted to the full limit of its capacity, consistent with its other imperative duties. In order, however, that the results may be placed before you in a manner carrying conviction of our earnest desire and intention to fully comply with the law, consistent with a strict adherence to the known scientific possibilities of the situation, an introduction to the main body of the report referring to these difficulties and to our present knowledge on the subject is respectfully submitted.

This introduction deals as briefly and yet as comprehensively as possible with the following subjects:

A. Our knowledge regarding the relation of the occurrence of typhoid and other infectious diseases to the eating of oysters and shellfish.

B. The results and the interpretations of investigations of the sanitary conditions of shellfish grounds, layings, etc., and the shellfish from the same, including the quotation of opinions of scientific workers and commissions regarding the present difficulty, if not impossibility, of fixing standards of pollution upon which condemnations may be based.

A. Relation of Oysters and Shellfish to the Causation of Typhoid Fever.*

Long before the advent of the science of bacteriology there were evidences to show that oysters grown or fattened in sewage-polluted waters were responsible for cases of typhoid fever in those who had eaten these oysters uncooked.

The earliest outbreaks of typhoid attributed to the eating of contaminated oysters were reported in 1816, but few other instances were placed on record until 1880. Since that date a con-
836 siderable number of definite outbreaks have been more or less conclusively shown to have been due to the eating of oysters and shellfish taken from polluted waters. In some places having a high incidence of typhoid fever investigators have attributed a considerable proportion of the sporadic cases of this disease, and in fact some have assigned actual endemic typhoid conditions to the eating of shellfish taken from polluted waters.

Concerning the evidence connecting some of the outbreaks of typhoid fever with the eating of oysters obtained from polluted waters there can be no serious question. That oysters obtained from or which have been "plumped" in sewage-polluted waters have caused outbreaks of typhoid fever is a fact which cannot be gainsaid.

The well-known outbreaks of typhoid fever attributed to oysters in this country occurred at Middletown, Conn., and at Atlantic City.

The Middletown outbreak occurred in the fall of 1894 and was responsible for commanding definite attention in this country to the transmission of typhoid fever by oysters from polluted waters.

The conditions and circumstances under which the outbreak occurred were exceptionally well adapted to prove the possibility and the probability of such transmission following certain lines of oyster industry.

The facts described by Conn* were substantially as follows:

Oysters taken from long Island sound were deposited for a few days, at least, in the tidal waters of Quinnipiac river at Fair Haven, Conn., about 300 feet above the outlet of a private sewer carrying sewage from a house in which there existed two cases of typhoid fever.

Some of these oysters were eaten raw at three separate fraternity banquets at Wesleyan University and served cooked at another fraternity banquet. All of these banquets were held the same evening. Twenty-five per cent. of those attending the three banquets where the raw oysters were served contracted typhoid fever. There

* In the Journal of the Franklin Institute, Vol. CLX, p. 81, August, 1905, Mr. George W. Fuller gives a full account and a very extensive bibliography of Sewage Disposal in Its Relation to the Pollution of Oysters and Shellfish and to the Transmission of Typhoid Fever by the Latter.

An exhaustive report on the same subject is to be found in the Fourth Report of the British Royal Sewage Disposal Commission, Vols. I, II and III.

* Conn. Seventeenth Annual Report, Connecticut State Board of Health, 1894, pp. 243-264.

were twenty-nine such cases. None of those attending the
837 other banquet were affected. There were likewise found two cases among those who had eaten oysters from the same lot in other places in Middletown.

Some of the oysters from the same location at Fair Haven were sent to an Amherst College fraternity dinner, held on the same evening, and six cases of typhoid fever among those attending followed.

No other cases occurred in either of these places which could not be satisfactory accounted for.

The period of incubation and the onset and course of the disease in these cases indicated most definitely a common origin, and there was found no other possible common source but the Fair Haven oysters.

This is a most typical example of the infection of oysters through "plumping" or "drinking" them in water polluted with typhoid discharges. The practice of "drinking" oysters at Fair Haven was not new at that time; the sewer responsible for the infection and other private sewers in the neighborhood had poured sewage into the river for years. The Quinnipiac is likewise polluted by sewage from other sources, but so far as is known the oysters plumped in its waters had not been responsible for a prior outbreak of typhoid fever. However, it would not be proper to infer that oysters plumped in these waters had not been the cause of cases of typhoid fever. Nevertheless, the advent of the two cases to one of the houses sewering into the river near the oyster floats brought about a pollution described by Houston as the most dangerous kind as it was "specific" in character and of "recent sort," although comparatively small in amount.

During the summer of 1902 at Atlantic City, N. J., an unusual number of cases of typhoid fever was noted by the medical profession of that place.

A thorough study of the situation showed that there was no common source for the infection other than oysters and clams. The oysters were found to have been floated in waters at the mouth of the Penrose canal and its vicinity, and this canal was ascertained to be carrying an unusual amount of sewage, owing to a break in the large sewer pipe running in the canal and which conducts
838 under ordinary conditions a considerable portion of Atlantic City's sewage to the "thoroughfare." That the oysters floated and the clams taken from these polluted waters were responsible for a large proportion of the unusual number of cases at Atlantic City there is no doubt. This conclusion was approved by several well-known bacteriologists and epidemiologists who investigated the situation.

In England, in recent years, two extensive outbreaks of typhoid fever, directly attributable to oysters, occurred at Winchester and Southampton from eating of raw oysters taken from lots floated in the proven polluted waters at Emsworth. Here, again, we have to deal with two banquets given on the same day in two separate municipalities, with no possible common source of infection other

than the oysters which were eaten raw. None of the guests contracted the disease except those who had eaten some of the oysters. Approximately, the same percentage of guests contracted the disease and at corresponding intervals. It was likewise found, as in the Middletown cases, that oysters from the same lot brought about infection with the disease among those eating them in other places. It is interesting to note that the oysters had been temporarily deposited in the polluted waters and had not reached maturity at this spot.

In the matter of the causations of sporadic cases and of endemic typhoid conditions by the eating of shellfish, the British Commission on Sewage Disposal obtained the opinions of a large number of well-known English bacteriologists and epidemiologists on the subject. The following are some of the more representative of these opinions, together with the final conclusion of the Commission:

"Dr. J. T. C. Nash.—From special researches made in 1902 into the causation of typhoid fever in Southend-on-Sea, Dr. Nash came to the conclusion that at least 50 per cent. of the cases in that year were due to the consumption of shellfish from sources contaminated by sewage. This, indeed, in his opinion, understates the limit, as he found that out of 105 cases of typhoid fever in that year there was some connection with shellfish in at least eighty-two cases.

"Dr. Nash also quoted figures of typhoid notification in Yarmouth for each month of the years 1897 to 1902. In 1900, after
839 a series of years of endemic typhoid in this town, the sale of mussels from the Yare was stopped, and in 1901, there was a marked reduction in the number of notifications (amounting to 30 per cent. below the monthly means of previous years), and in 1902 a still further reduction.

"Dr. A. Newsholme.—Submitted a tabular statement of the number of cases of enteric fever in Brighton during the years 1894 to 1902, distinguishing those which, in his opinion, were caused by oysters and other shellfish. This table indicates that, out of 643 cases, 158 cases were directly ascribable to the consumption of oysters, and eighty cases to the consumption of other shellfish within the period of incubation. In other words, that 37 per cent. of the total cases of enteric fever during these years were ascribable to shellfish. The history of each case was traced, and cases of typhoid fever were only put down to the shellfish after the apparent exclusion of every other possible cause. The shellfish were traced to particular layings which were proved to be exposed to sewage contamination, and typhoid fever was found to exist among the population draining to the vicinity of the layings. In the opinion of Dr. Newsholme, the extent of the illness attributable to shellfish is understated in the above figures.

"Dr. James Niven.—Submitted a tabular statement of the number of cases of enteric fever in Manchester during the years of 1897 to 1902, inclusive. This table shows that in that period there were 2,664 cases of enteric fever, of which number 274 were associated with the consumption of shellfish, 118 being strictly ascribable to mussels and oysters. In arriving at the latter figure, all other possible causes were considered, and all doubtful cases were rejected. Owing

to gaps in the figures, the number of cases due to shellfish is probably understated.

"Mr. Shirley Murphy.—The information supplied by medical officers of health of metropolitan boroughs tended to show that in 8 per cent. of the cases of enteric fever which occurred in London in 1902, the patient had eaten shellfish at a time before the attack that was consistent with such shellfish having been the cause of the disease. It was not possible, however, to make a definite statement as to what the proportion really was, and Mr. Shirley Murphy was inclined to think that 8 per cent. fell short of the number that
840 would have been obtained if full inquiries could have been made.

"Conclusion of Commission as to Extent of Illness Attributable to the Consumption of Contaminated Shellfish.

"29. After carefully considering the whole of the evidence on this point, we are satisfied that a considerable number of cases of enteric fever and other illness are caused by the consumption of shellfish which have been exposed to sewage contamination; but, in the present state of knowledge, we do not think it possible to make an accurate numerical statement.

"Moreover, an examination of the figures which have been placed before us as regards those towns in which the subject has been most carefully studied shows that there may be occasional errors. Indeed, the witnesses themselves recognized that absolutely accurate figures are not obtainable.

"We are far from denying that isolated cases may have been due to contaminated shellfish, but when we remember the numerous unexplained cases of enteric fever, we feel that the possibility of some of them being due to other causes cannot be altogether excluded."

In this county, opinion on this subject has not become sufficiently crystallized to have brought out many reports of investigation.

The most important is, perhaps, that made by Mr. George A. Soper* regarding typhoid conditions at Lawrence, L. I., in 1904. In this study, the investigator found twenty-one out of thirty-one cases of typhoid fever in which the only probable sources of infection were oysters and clams taken from floats immersed in polluted waters, or from oyster beds subject to pollution. In the majority of cases at least, the oysters were from the floats.

That the waters in which these floats were located were badly polluted was amply demonstrated by the chemical and bacteriological examinations made at a time when conditions were known to be far better than when the cases of the disease developed.

Samples of oysters were likewise examined bacteriologically, and of them 25 per cent. were shown to contain bacteria of the bacillus coli communis type in one-tenth of a cubic centimeter of
841 the shell water, and in 60 per cent. in one cubic centimeter of the same.

The sanitary survey showed the discharge of imperfectly treated sewage, from a population of 15,000, less than half a mile from the

* Soper. Medical News, Vol. 86, 1905, p. 241

oyster floats. In fact, some were very much nearer. Aside from this pollution, there were many individual sewers, manure piles, dump heaps, piles of cesspool sludge, which contributed to the pollution of the water adjacent to the floats.

B. The State of Our Knowledge Concerning the Relation of Qualitative and Quantitative Estimations of Pollution of Water and Shellfish to Disease-producing Liability of the Latter in Man.

From a study of the outbreaks of typhoid fever proven and suspected of being caused by oysters, and of endemic conditions and sporadic cases of this disease caused and suspected of being caused by the consumption of infected shellfish which have been already described, it is apparent that in almost all the instances quoted in the former group, and to a large extent those in the latter, were due to the almost direct carriage of materials of a demonstrated or readily assumed specific infectious typhoid or other disease-producing nature to the shellfish.

The fact that the great danger of the transmission of typhoid fever and other diseases by means of shellfish lies in the character of the materials polluting the beds, drinking places, etc., and in the directness with which such pollution reaches the shellfish, has been well expressed by Hanston in the Fourth Report of the British Royal Sewage Disposal Commission, Vol. I, p. 36, where he is quoted as saying as follows:

"A pollution trivial in amount but specific in character is much more dangerous than a contamination gross in amount but non-specific in nature.

"It is also probable that a pollution trivial in amount, but specific in character and of recent sort, is more dangerous than a pollution gross in amount, specific in character, but of remote kind."

If then the important factors in the role which shellfish play
842 in the transmission of diseases are the character of the materials polluting them and the directness of the pollution, it is manifest that to be in a position to definitely pass upon the disease-producing value of a given growth or lot of shellfish, we must be in a position to determine with accuracy not only the presence or absence of specific disease-producing pollution and also the directness with which such materials will gain access to the shellfish, but also we must be able to express in a quantitative degree the possibility of such specific pollution and the directness of its carriage to the shellfish. Unfortunately neither our systematic supervision of infectious diseases, our methods of sanitary inspection of sewerage and waste disposal systems, nor our technical methods of determining, as a routine procedure, the presence or absence of pollution in water or shellfish, permit us to make definite estimates of the possibility of specific typhoid pollution of shellfish.

To be more explicit on these points, it may be said that while the medical profession and health officers endeavor to prevent undisinfected discharges from typhoid patients and convalescents, from gaining access to sewage and thus to tidal waters, there is no doubt

that such discharges do gain access to such waters with frequency. But how frequently, it is impossible to state.

Typhoid fever is not by any means confined to the larger centers of population with sewerage systems emptying into tidal or other waters. Indeed, the reverse is true. It has been shown by Fulton, Egbert and others quite conclusively that the disease is relatively more prevalent in rural communities. Here individual systems of sewage disposal are in vogue. The greatest danger to a water supply, and by inference to oyster beds, is not, therefore, of necessity due to the presence of sewage from a large community. Most of the outbreaks of this disease due to polluted water have been caused by the improper disposal of the discharges of but one or two cases. This is likewise the case, but to a lesser extent, in the epidemics due to polluted shellfish which have already been described.

However, even a knowledge of the number of cases of typhoid fever among a population using a particular sewerage system permits only approximate estimation of the actual infectious character of the sewage in that system at its outlet. It is well recog-
843 nized that some individuals not sick with this disease harbor and distribute the germs of it in their discharges. Therefore, for this and other reasons the estimation of the amount of sewage leaving a system of disposal is not in reality an accurate index of the "disease value" or infection "possibilities" of that sewage.

Moreover, the laboratory investigations of water sewage and shellfish furnish but little better evidence as to the specific character of a pollution, for the reason that there has never been devised a practical method for the routine determination of the presence or absence of specific disease-producing germs in such materials. All that is now undertaken in such investigations is the determination of the amount of organic matter capable of being used as a bacterial food in the water or sewage, as measured by the number of bacteria present, and the presence or absence and the quantitative estimation of the common sewage bacteria, chiefly and usually only those of the bacillus coli communis type. In other words, the laboratory measures the degree of sewage pollution but not its specific disease-producing character.

The same difficulties which have made impossible for the present the routine examination of water and other liquids for the specific disease-producing bacteria, particularly the typhoid bacillus, have likewise made it most difficult to obtain conclusive results from experiments conducted with the view of showing the fate and the duration of life of the typhoid bacillus in sewage, waters of various types and in the bodies of shellfish. However, a very considerable amount of research has been conducted by bacteriologists toward the settling of the various aspects of this special problem, and the following may be considered a brief but fair general statement of the results:

It may be said that so far as available evidence goes, the living typhoid bacillus does not multiply in either fresh or sea water or oysters under natural conditions.

Whipple has concluded from a study of the literature that the duration of life of the typhoid bacillus in salt water is not unlike that in the fresh. It is generally conceded that the life of the typhoid bacillus in fresh waters of various types is not of long duration, depending upon the action of sunlight, absence of oxygen, antagonism of other bacteria and other physical agencies.

844 Savage has shown that its life in tidal mud, under various conditions, is greater than in water from the same locations, but that, at least, the vast majority of them perish in two to three weeks.

Klein, Field and others have found that typhoid bacilli in live oysters in sea water under certain conditions do not have an indefinite existence but die in considerable numbers, and cannot, in general, be found after a few weeks.

It is, of course, understood that in all such experimental work, the difficulties of isolating typhoid bacilli from fluids containing other bacteria make it possible for some, at least, of the typhoid organisms to have remained alive and to have escaped detection. It can be said also that it is generally conceded that the bacteria of the species type of the bacillus coli communis, the most common form of bacteria found in human discharges, has at least as long a duration of life under most natural conditions as the typhoid bacillus; and that as a general rule it resists the destructive forces of such agencies for a longer period.

For these and other reasons, it must be admitted that the relative numbers of B. coli and other sewage bacteria present in water, milk and other articles of food and drink, gives us indices of a comparative and relative character of the fecal pollution of those articles. While this statement is not likely to be seriously controverted, it must not be forgotten, as we have already indicated, that the degree of pollution, as measured by the relative presence of bacillus coli or coli-like organisms as determined by present methods, is not of necessity an index of the disease-producing power of the polluted article.

From what has been said, it can be properly inferred that the sanitary inspections and the laboratory investigations can give a better idea as to the directness of general sewage pollution than of its specific character, but here again such determinations only have significance as indicative of probabilities and not as certainties in so far as the production of disease is concerned.

The British Royal Sewage Commission in the report already referred to, after carefully weighing a vast mass of evidence, makes the following statement in their conclusions on this aspect of the subject:*

845 "We find it very difficult to state to what extent bacteriology is to be relied on for the purpose of distinguishing those foreshores, pits, ponds, beds or layings from which shellfish are procured, which may be considered safe from those which should be regarded as unsafe, from the point of view of public health.

* Vol. I, p. XXXVI.

"The methods at present available to the bacteriologist do not permit of his detecting, except possibly in very rare cases, the typhoid fever micro-organism either in sewage largely diluted with sea water or in shellfish; neither do they enable him to measure, in any exact manner, whether the micro-organisms which he takes as his index of danger are of recent or remote intestinal origin. Moreover, there is no constant ratio between the numbers of the organism taken as an index and the numbers of the disease-producing organism in the typhoid intestine, in the raw sewage or in the mixture of sewage and estuary water.

"Mere numbers of B. coli or any other particular micro-organism of sewage cannot, therefore, be said to have anything approaching an exact value as an indicator of the danger of disease, and we consider that before any working bacteriological standard can be applied to this problem further knowledge is necessary."

If these statements apply to the bacteriological data, how much more do they generally apply to the results obtained by the less specific methods of measurement of pollution utilized by the sanitary engineer and inspectors.

The limitations of all branches of science in these directions have been summarized by Dr. Houston, the bacteriologist of the British Commission, who has made most exhaustive studies of shellfish pollution, in the following phrase: "Neither the epidemiologist, nor the topographist, nor even the bacteriologist can assign a definite disease value to a given pollution."

It is evident, therefore, that no attempt should be made to pass judgment of condemnation or approval upon shellfish beds and their contents, from the basis of the existence or freedom from disease-producing conditions in them, for we have no method of definitely determining such conditions.

We are forced, therefore, to rely for such action as may be advisable upon the basis of the estimation of the amount and distribution of the sewage pollution of a general character in relation to
846 shellfish beds and their contents, and to oyster drinking places. Nevertheless, making such a basis for action is fraught with no little danger, for the reason that the basis is an artificial one; and on the one hand, it is entirely possible that approval may be given under it to beds, drinking places, and indirectly to oysters and shellfish, which may become the means of transmitting disease; and on the other hand, it is more than likely that beds, etc., may be condemned which are not in reality a menace to health and will not likely become so. In fact, justice to the oyster industry on the one hand, and to the public health on the other, demands that action on this basis shall not be taken except after the most careful and exhaustive investigations of an epidemiological sanitary engineering and biological character.

In order that the opportunities for error and the difficulties of setting up and maintaining such an artificial standard may not be minimized, it is but fair to state that the British Royal Sewage Commission before making their report on the subject had spent about four years in the study of the problems of the pollution of the

oyster beds of the countries of that empire, and that the scientists and medical officers of health who testified before the Commission or worked under their direction had in some cases been debating and investigating the subject for ten years. It was the opinion of the Commission and of the scientific workers that they had not yet sufficiently covered the ground to warrant the establishment of a standard of pollution sufficiently definite for the condemnation or certification of the insanitary or sanitary condition of oyster and shellfish beds and shellfish.

The Massachusetts State Board of Health likewise spent four years in the study of the pollution of Boston harbor before they undertook to prohibit the taking of shellfish from most sections of it, and even when such action was taken they did not refer to any definite standards as a basis for their decision in the matter.

For this Department to attempt to fix standards of pollution for condemnation after a few months' work, with no adequate financial support, and a field for investigation almost equal in area and importance to that covered by the British Commission investigation, would indeed be presumptive.

It can be said, however, that the results obtained by the
847 sanitary survey and the biological investigations of the laboratory, both of which must be considered in the light of preliminary studies, exhibit a very fair degree of harmony. This harmony would appear to indicate that a more satisfactory basis for drawing conclusions as to the relative pollution of a general character of the various locations might be obtained by more thorough studies which could be made if proper resources are provided.

Sanitary Survey of Shellfish Grounds.

The engineering work undertaken in the investigation comprised the collection of data and the preparation of maps to show:

I. The character, amount and points of discharge of all pollution received by streams, tidal rivers, bays and sounds which might cause contamination of shellfish.

II. The location of all leased oyster beds and the waters from which oysters and clams are taken for market.

III. The estimated yearly output of marketable and seed oysters and of clams from each district or shipping point.

IV. The general direction of tidal currents in Jamaica bay, with reference to the principal points of pollution, by a short series of float experiments, together with the determination of the tidal prism in Jamaica and Raritan bays.

The method of procedure and the work accomplished under each of the foregoing headings will be described in detail.

I. Collection of Data Regarding Pollution.

Complete data were secured by personal inspection made by inspectors from this Department as to the pollution of all streams,

tidal rivers, bays and sounds which might affect the shellfish industry carried on in waters adjoining Long Island and Staten Island comprising all oyster cultivation districts within New York State.

The data thus collected describes, it is believed, all public and private sewers and overflow pipes from cesspools discharging into such waters, and all outside privies located near the bank of streams and bays, together with other special conditions, such as the character and amount of wastes from manufacturing plants and the location of refuse dumps, which might contaminate such waters.

848 All municipalities were visited and practically a house-to-house canvas was made along the shores and streams of Long Island from College Point on the East river easterly to Orient Point, Riverhead and Montauk Point, and thence westerly to Coney Island, comprising some 400 miles of shore line; such inspection was also made along the shores of Staten Island from the Narrows westerly to Tottenville, and northerly to Linoleumville. In addition, data was obtained as to the sewage pollution from New Jersey municipalities discharged into Raritan bay, Shrewsbury river, Raritan river, Rahway river, West brook and Arthur kill.

In this work of inspection to determine pollution, the data collected included: (*a*) The location or point of discharge of all public and private sewers, cesspool overflow pipes, outside privies and sewers carrying wastes from factories; (*b*) the number of persons served by each sewer or sewer system; and (*c*) the date of construction, when available, of each sewer and sewer system.

This data was recorded in daily reports of inspectors made in duplicate on blanks numbered to correspond to numbers shown on inspector's maps. In order to be able to show graphically on maps the results of the sanitary inspection a numerical system was adopted as follows: A number was assigned to each stream, bay or locality, and the points of pollution were numbered on maps to correspond to the numbers on inspectors' reports. The character of the pollution is indicated by a decimal number affixed to the number assigned to the locality—.1 indicating a public sewer system outlet; .2 indicating a private sewer; .3 indicating an overflow pipe from a cesspool; and .4 indicating an outside privy over the water or in such a location as to pollute the water. Subnumbers indicate the number of separate cases of sewers, privies, etc., in each locality or on each stream or bay. For instance, 109.2, indicates eight private sewers discharging into the stream assigned the number 109, and 109.3, indicates eight cesspool overflow pipes discharging into the same stream. In some instances individual cases of pollution were indicated by letters, for instance, 260.2^a, and 260.2^b indicates two private sewers discharging at separate points into the same stream.

The daily reports of inspection, signed and dated by the inspector, are numbered to correspond to the numbers on the map indi-

849 cating pollution, and give further detail of such pollution.

These reports of sanitary inspection appear in this report as Appendix II. The pollution data given in the inspector's daily reports is summarized for fourteen separate oyster cultivation districts

and appears, together with the results of sanitary analysis of water and oysters, in Appendix I to this report.

The inspectors' maps, for use in the field work, were made up by mounting and folding the Atlas sheets of the United States geological survey covering the entire tidal waters of New York State, from Arthur kill to Fishers island. From these maps and from maps of the United States coast and geodetic survey tracings and prints have been made to accompany this report, and will be found in Appendix I and III.

Much valuable assistance was rendered during the investigation by health officers and other public officials of various towns and villages.

II. Location of Oyster Beds.

Maps showing the location of all oyster beds leased by the Marine Fisheries Department of the New York State Forest, Fish and Game Commission, by the various towns in Nassau and Suffolk counties, by the county of Suffolk, and by the heirs of the Smith Estate (in Great South bay) were obtained or traced from existing maps and these bed locations were transferred to one of the inspectors' maps. No maps of oyster grounds in Manhasset bay on the north side and Hempstead bay on the south side of Long Island were available, and the map of oyster beds in Great South bay, leased by the town of Islip, did not show the location of the beds in relation to the shore lines. However, in these three instances the approximate location and extent of the beds were obtained from oyster commissioners and oystermen and are shown on the maps. The location and extent of all leased oyster beds, with notes as to natural growth oyster grounds, are shown, therefore, on the maps appearing in Appendix I and III, although it was found that the use of many of the beds had been discontinued in some localities.

The oyster beds leased by the State comprise all beds in Jamaica, Raritan, East Chester and Pelham bays, and those in Long Island sound which lie outside the bays and harbors. In general, all other oyster beds in New York State are leased by the towns in which they lie, except that the beds in the Peconic bays, Gardiner's bay, and Shelter Island sound are leased by the county of Suffolk, and except that certain beds in Great South bay from Nicholas Point eastward to Bayport, included in the towns of Islip and Brookhaven, are leased by the heirs of the Smith Estate. The locations of oyster beds in Jamaica and Raritan bays were taken from prints furnished by the New York city health department made from tracings of the maps on file in the Bureau of Marine Fisheries.

The location and extent of the leased oyster beds in the fourteen oyster cultivation districts in New York State are described in detail in Appendix I of this report.

III. Statistics Showing Yearly Output of Shellfish.

The United States Bureau of Fisheries in the last published "Statistics of the Fisheries of the Middle Atlantic States" reports that in 1904 the total yield of shellfish from New York State waters was as follows:

Oysters, 3,329,332 bushels, valued at $3,780,352, of which 2,868,507 bushels were market oysters and 460,825 bushels were seed oysters.

Hard clams, 167,992 bushels, valued at $303,599.

Soft clams, 74,993 bushels valued $95,400.

Scallops, 148,799 bushels, valued at $145,646.

Skimmers or surf clams, 11,510 bushels, valued at $6,720.

Mussels, 15,910 bushels, valued at $4,590.

In the same report it is stated in relation to the oyster industry in New York State: "The increase in the value of the products (of all fisheries) from $3,894,270 in 1901 to $6,230,558 in 1904 is due principally to the extension and success of oyster culture. In 1904, 2,847,792 bushels of market oysters were taken from the private areas and only 20,805 bushels from the natural reefs, a remarkable exhibition of the development of the cultivated grounds. As regards the value of the output, New York is now the foremost American State in oyster culture. The recent growth of this industry has been especially extensive at the eastern end of Long Island. Previ-
851 ous to 1900, oysters shipped from that region were planted elsewhere before marketing but in recent years they have been permitted to remain until large enough for market. Of the market oysters credited to the private areas of the State, 378,410 bushels, worth $404,135, and of the seed oysters 46,150 bushels, worth $39,670, were taken up by vessels owned in Connecticut and elsewhere outside of New York."

The total output of market oysters for 1904 from the Middle Atlantic States—New York, New Jersey, Pennsylvania, Delaware, Maryland and Virginia, was 14,429,974 bushels as given by the Bureau of Fisheries at Washington.

In connection with the sanitary inspection, estimates were secured when possible of the probable output of market oysters, seed oysters and clams from each locality. The data thus collected appears on the inspectors' reports and is summarized for each district in Appendix I.

IV. Determination of Tidal Currents and Volumes.

But little time was available during the investigation to carry out float experiments for the purpose of determining the direction and velocity of tidal currents as relating to the distribution of sewage in waters in which oysters are grown. However, a series of float experiments was made, extending over a period of ten days, to determine the probable course followed by sewage and sewage disposal plant effluent discharged at four of the principal points at which Jamaica bay receives pollution.

It should be stated that the determination of tidal currents and velocities, if definite results are to be obtained, requires that an extended series of float experiments and calculations covering a considerable period of time should be carried on under varying conditions of tide and winds.

The points at which floats were liberated were at the Sheepshead Bay sewage disposal plant outlet near Plum Beach channel; at the point of outlet of New Lotts sewage disposal plant northeast of Canarsie; at Bergen creek which receives the effluent from the Jamaica sewage disposal plant; and at various points in Beach channel along Rockaway Beach.

From what little information could be obtained in the ten
852 days during which experiments were carried on, as to the direction and velocity of tidal currents in Jamaica bay, it would seem probable:

1. That effluent from the Sheepshead Bay sewage disposal plant, discharged at flood tide, passes into the upper reaches of Plum Beach channel northwesterly from its junction with Broad creek, and that effluent from this plant, discharged at ebb tide, passes out of Rockaway inlet only through Plum Beach channel and Dead Horse inlet.

2. That effluent discharged from the New Lotts sewage disposal plant at the beginning of ebb tide follows a course to points opposite Canarsie Landing, keeping from 100 to 1,500 feet off shore during this course, and from Canarsie Landing gradually swings out into a deeper channel east of Bergen beach reaching points from 1,000 to 2,000 feet east of Bergen beach in about three and one-half hours.

3. That effluent from the Jamaica sewage disposal plant reaching Bergen Creek during the beginning of ebb tide passes westerly of the Rockaway Beach railroad being 1,000 feet or more off shore at this point. This effluent then swings southerly into Pumpkin Patch channel and the adjacent channel to the west.

4. That sewage discharged into Beach channel during flood and during the last of the ebb tide from various points along Rockaway beach has a tendency to hug Rockaway beach shore during the corresponding flood tide. But that sewage discharged into Beach channel during the first part of the ebb, though passing along the Rockaway beach shore during the ebb, becomes disseminated across the channel during slack water and the beginning of flood tide, and is then carried back through Beach channel, or northeasterly up through the various other channels.

Tidal Volumes.

The tidal prism of Jamaica bay inside of Rockaway point and the Sheepshead bay breakwater was obtained by measuring the area of the bay on the United States coast and geodetic survey maps. The area of the bay, exclusive of marshes, is 16,690 acres. The mean range of tide is 4. feet. So that the total volume of tidal water passing in and out of the bay twice each day is, roughly, 2,900 million cubic feet.

853 Similarly the tidal prism of Raritan bay, Sandy Hook bay and that included portion of lower New York bay lying westerly from a line drawn from Sandy Hook beacon to Fort Tompkins light is, roughly, 11,500 million cubic feet, the area being 56,620 acres and the mean range of tide 4.7 feet.

Extended field work and studies are needed to determine the direction, volume and velocity of tidal currents in these and other waters of the State in which shellfish are grown and matured.

The Bacteriological Investigations of Shellfish Grounds.

These investigations consisted in the following undertakings:

1. The general survey and study of the oyster industry in the various localities in the State, and consultations with representative scientific workers in shellfish bacteriology, oysters growers, health officers, and others interested, in order to form a proper conception of the problem as a whole.

2. The inauguration of a central laboratory for the conduct of the biological researches as to relative pollution of the waters in the vicinity of oyster beds, and of oysters.

The general survey comprised visits to the oyster beds and consultations with representative oyster growers and health officers in the vicinity of Raritan, Jamaica, East Chester, Great South, Huntington and Oyster bays, and in the district comprising Peconic bay, Shelter Island sound and Gardiner's bay.

Much general and considerable detailed information regarding the oyster and clam industries was obtained, and led to decisions as to the course of the investigations finally followed.

It was ascertained that to attempt to undertake the investigation of the natural hard clam beds and their contents would be to so divide the available energies that only very unsatisfactory and incomplete results could be obtained from either the investigation of the oyster beds and oysters or that of the clam beds and clams. As the clam industry represents less than 1 per cent. of the volume of that of the oyster, it was deemed best to defer the study of the clams and their surroundings until a later period.

It appeared from the knowledge obtained during this general survey that oysters in Raritan and Jamaica bays finished spawning earlier than those in other sections of the State. In conse-
854 quence, these oysters were found to arrive at a marketable condition in advance of others. It was, therefore, believed that it would be easier to obtain samples of oysters in proper physical condition from these locations earlier in the season than from other sections. Moreover, the size and importance of the industry at these two points, and the apparent proximity of these locations to the large centers of population, led to the decision to make as extensive investigations in these two sections as the facilities and time at our disposal warranted.

It was likewise decided to undertake the examination of samples of water and oysters to be taken from other locations, selecting as far as possible such as would be most likely to show the more serious

pollutions and those which might reasonably be suspected of freedom from pollution.

The collection of samples was commenced the latter part of July and continued until October 1st.

The oyster samples were, in large part, collected through the courtesy of the various oyster producers by the sanitary chemist of the State Hygienic Laboratory, and the data regarding the locations from which they were collected and the conditions of collection are as complete as it was possible to obtain them with the facilities at hand.

The total number of samples of all kinds examined was 332. Of these, 128 were of water and 204 were of samples of oysters. In all 926 oysters were subjected to bacteriological examination.

The Bacteriological Study of Oysters and Their Surroundings.

The detailed results of these laboratory investigations in each of the fourteen oyster cultivating districts will be found in association with results of the sanitary surveys of these districts.

Descriptions of methods employed:

a. The oysters were first cleaned and a spot near the hings on the shell was sterilized by heat. With a drill sterilized by heat, a hole was drilled partly through the upper shell. The place where the hole was partly drilled was again flamed, as was the drill, and then the hole was drilled completely through the shell. This made it possible to draw off the shell water with a pipette from a point near the oyster's mouth.

855 *b.* As a test for bacilli of the B. coli type, the shell water was then inoculated into Jackson's bile media, and from the bile tubes which showed fermentation, lactose litmus agar plates were made and slants were made from typical colonies.

The results of tests for bacilli of the B. coli type shown in the tables of the Appendix are presumptive, as in only a few instances were confirmatory tests made from the agar slants.

The results that were obtained by confirmatory tests were generally positive.

The samples of water that were examined were also inoculated into Jackson's bile media. Early in the investigation it was found that bacilli of the B. coli type were so prevalent in the shell water of oysters taken from certain localities when 1 c. c. of the shell water was inoculated, that it was realized that there would be few quantitative distinctions, unless different volumes of the shell water *was* inoculated from oysters taken from a given place.

c. Afterward different volumes of the shell water were inoculated in the bile tubes; but because it was necessary to minimize the amount of work, the volumes taken of oysters from given localities were varied according to the location, and the conclusions derived from a knowledge of the locality.

In places where the sanitary survey indicated that the oysters might be more seriously polluted, 1/10 and 1/100 c. c. inoculations

were made. From four to six oysters from a given bed were usually examined.

Approximate quantitative B. coli type results were also obtained upon the samples of water from the oyster beds by inoculating different volumes in a similar manner.

On the water samples, bacterial counts were made upon standard gelatin incubated for forty-eight hours.

Comments upon the Results of the Sanitary Examinations and the Bacteriological Investigations.

In view of the statements made under sections A and B in the preliminary remarks of this report, it must be manifest that even if the investigations here reported had been carried out over a period of years and with the greatest care allowed by our present scientific methods, it would not be possible to draw conclusions as
856 to the presence or absence of disease-producing power of the oysters from the results here reported.

As has been stated, while the results of the field and the laboratory work are in close harmony, the studies can only be considered as preliminary, and as such the Department is not warranted in passing final judgment on the results for the purpose of administrative action. This does not carry with it, however, the necessity for refraining from the tabulation of the results on the basis of the relative conditions as found.

Certain workers in bacteriology have undertaken to classify the results of the examination of oysters by groups, and have referred to the results placed in certain groups as being subject to degrees of pollution.

Thus Houston* in his published article on shellfish pollution outlines six groups on the basis of his findings of bacillus coli communis in the whole oyster.

The table expressing these groups is here reproduced, and in its provisions and statments gives a tabulated conception of the whole problem of the fixation of standards.

---

* Houston. Journal of Hygiene. 1904. Vol. 4. p. 182.

† It must, of course, be definitely understood that it cannot be said that oysters of Class II or even Class I are necessarily always safe, or that oysters of Class III–VI have a definite "disease value."

No. 1. To obtain approximate results per c.c. of oyster, divide the foregoing figures by ten.

No. 2. The approximate results per c.c. of oyster have been computed and expressed in terms of volume of oyster in which B. coli is present are here inserted in brackets in Dr. Houston's table.

No. 3. This does not mean administrative, practical or legislative condemnation, but only that the evidene of pollution is sufficiently defined to merit objection from the bacteriologist's point of view.

No. 4. As regards tests (1), (2), (3) and (4), my work for the Local Government Board on the B. coli of recently voided normal human faeces shows that of 100 B. Coli, 98, 92, 98 and 92 per cent. yielded positive results in each instance to one or other test. As regards all four tests (taken in conjunction) 85 per cent. yielded positive results.

Bacteriological Grouping of Oysters.

Class.	Standard based on numerical abundance of B. coli (or non-liquefying, gas-forming coli-like microbes), in the whole contents of the oyster shell (i. e., liquor, body and interior juices of the oyster).
I.	
An oyster showing no evidence (bacteriologically) of objectionable contamination.	No B. coli.
II.	
An oyster showing appreciable, although slight, evidence (bacteriologically) of objectionable contamination.	1 B. coli per oyster No. 1. No. 2 (approximately, B. coli in 10 c. c. of oyster).
III.	
An oyster, showing definite signs (bacteriologically) of pollution and, therefore, possibly to be viewed with some degree of suspicion.	10 B. coli per oyster No. 1. No. 2 (approximately, B. coli in 1 c. c. of oyster).
857 IV.	
Stringent standard: An oyster showing such obvious signs (bacteriologically) of pollution as to be condemned on a stringent standard.	100 B. coli per oyster No. 1. No. 2 (approximately, B. coli. in 1/10 c. c. of oyster).
V.	
Lenient standard: An oyster showing such unmistakable evidence (bacteriologically) of pollution as to be condemned on the basis of results No. 3.	1,000 B. coli per oyster No. 1. No. 2 (approximately, B. coli in 1/100 c. c. of oyster).
VI.	
An oyster showing such gross evidence (bacteriologically) of contamination as to be outside the pale of recognition.	10,000 B. coli per oyster No. 1. No. 2 (approximately, B. coli in 1/100 c. c. of oyster).

In Classes with Tentative.

Numerical standard confirmed or modified according to response of the coli-like microbes in pure culture to certain well-known biological tests:

For example:
(1) Neutral-red broth test—
Greenish-yellow fluorescence (48 hours at 37° C).
(2) Lactose peptone test—
Gas and acid productions (48 hours at 37° C).
(3) Indol test—
Indol in broth culture (5 days at 37° C).
(4) Litmus milk test—
Acid clotting of milk (5 days at 37° C).

Of course, the more tests applied, the better, but the above are all known tests of value No. 4.

858 Standards for Comparative Purposes.

Provisional bacteriological conclusions confirmed or modified by topographical observations.	Provisional bacteriological and topographical conclusions confirmed or modified by epidemiological and administrative considerations.
For example: Dilution: set of the tides; prevailing winds; float experiments; time interval; distance, etc., etc.	For example: Questions of practicability; whether the contaminating material is likely to have a high or a low enteric morbific value; past epidemiological experience in circumstances broadly parallel, etc., etc.

For the purposes of comparison, we may take the work conducted under the direction of the Massachusetts State Board of Health,* which has already been referred to. As has been stated, this work was in progress for several years. The only instance of the condemnation of any location as a source for the production of shellfish by this Board is that of Boston Harbor. It is of interest, therefore, to note the results of the sanitary survey and of the examination of shellfish and water from the same, and the grounds upon which the condemnation was made.

The sanitary survey showed that approximately 170,000,000 gallons of sewage were poured into the waters of the harbor at three points daily, and that also a considerable amount was contributed at a large number of other points, but no estimates of those amounts

* 37 Annual Rept. Mass. State B. of Health, 1905. p. 16, 411-58.

were given. It should be stated that 100,000,000 gallons of the sewage is sent out to sea with the outgoing tides. Nevertheless, it is stated that the waters of the harbor are subject very generally to considerable pollution. Apparently were it not for the marked purifying action of the tides, the harbor would soon be in an intolerable condition. However, it is stated in the report that the incoming tide returns none of the previous outgoing pollution with it.

859 Regarding the laboratory examinations of the water and shellfish, the report is not specific as to the exact bacteriological methods used in the tests. In the key on the map are the statements that the results for the tests on the clams are B. coli in 1 c. c. of the shell water or in the body of the clam. No figures are shown, however, on the map, the results being indicated by + or 0 signs, indicating, respectively, the presence or absence of B. coli presumably in 1 c. c.

In the table on page 424, the results are given in terms of samples containing various sewage bacteria in either shell water or the bodies of the clams, presumably again in 1 c. c. Examining these results, we find out of 125 samples of clams examined all but twenty-nine showing the presence of either B. coli or sewage streptococcus in either the shell water or body of the clams, and in only four instances were there less than 50 per cent. of the samples from a given place showing these bacterial evidences of pollution. In only fifty-six samples out of 125 were B. coli found in the shell water of the clams. It should be stated, however, that in the work reported in other parts of this volume, there are statements leading to the conclusion that in many shellfish from the most polluted sources the B. coli were not to be found in the shell water or the body of the clams. In such locations the usual presence of streptococcus gave indication of the possible overgrowth of B. coli by the latter. As this is an experience which we did not note in our work, it is possibly due to a difference in the methods employed.

Taking all these facts into consideration, it might be arbitrarily assumed, merely for the purpose of comparison of results between the various workers, that the condemnation limit, as far as bacteriological work is concerned of the Massachusetts State Board of Health were probably not far from the presence of the B. coli type in 1 c. c. of the shell water of shellfish examined.

In the report of the bacteriological examination of oysters of Narragansett bay, conducted by Mr. C. A. Fuller for a period of three years, the author draws distinction between those containing B. coli in the shell water or body of the oysters and those which do

860 not. He speaks of the former as polluted, and the latter as not polluted. He makes no attempt at quantitative examinations of the B. coli content of either the shell water or of the various portions of the body of the oysters examined. However, it is a fair inference that quantities less than 1 c. c. must of necessity have been used by him in the tests of the intestinal and visceral content of the oysters. This might well account for his finding B. coli less often in the oysters than in the water over the oysters. In the water exam-

inations from which he drew his conclusions as to the presence or absence of pollution, his analyses were of 1 c. c. samples.

It can properly be assumed, merely for the purpose of comparison, that a maximum limit which would fairly represent the views of this worker would be the presence of B. coli in 1 c. c. of either tidal water or the shell water of the oyster.

In the report of Soper on the typhoid conditions at Lawrence, he mentions oysters showing a presumptive test for B. coli in 1 c. c. of the shell water as probably polluted, and those showing B. coli in the same way in 1/10 c. c. as definitely polluted. This latter would correspond somewhat to Houston's stringent standard.

In order to compare the results obtained by our own investigation from the various locations with each other according to these various tentative and presumptive standards of the authors quoted, the following table has been prepared.

The plus (+) indicates that if such standards as have been here attributed to the various authors were applied to the results obtained by us and were to be accepted as a basis for condemnation, the oysters from that section would come under the ban. The minus (—) sign indicates that the reverse would be the case.

It would not be proper for us to assume that the authors under consideration would be willing to assume responsibility for the application of these standards in such a manner, but the table serves well to illustrate the fact that while diversity of opinion may exist in different locations, according to variations in the presenting problems, there is not so great a general divergence from the different standards as might be expected.

[1] Massachusetts. Assumed Massachusetts State Board of Health standard for condemnation = Bac. coli type present in 1 c. c. volumes of shell water of 50 per cent. of samples examined.

[2] Fuller. Assumed standard of C. A. Fuller, Rhode Island Investigation = B. coli present or absent in 1 c. c. volumes of tidal water or oyster shell water as indicative of the presence or absence of sewage pollution.

[3] Houston. Presumptive stringent and lenient standards of Houston. It should be stated that Houston's technic and methods of expression of results as indicated in the table quoted from his work are not those used by us, and it would not be possible to interpret our results in the terms used by him with absolute accuracy. He examined the entire contents of the oyster shells, while we examined only the shell water. Broadly speaking, however, we may reasonably assume that his stringent standard would be about equivalent to the finding of B. coli in .1 c. c. of shell water and his lenient standard to the same finding in .01 c. c. of the same.

862 It must be remembered that the above interpretations have been based upon the results of laboratory analyses alone and have not been considered in relation to the important factors involved in the "Sanitary Survey," the information and bearing of which have always been taken regularly into account by all commissions and other official bodies which have worked on this problem and have had to assume the responsibility of drawing conclusions and making recommendations for official action. In fact, when we stop to consider the indefinite nature of the evidence furnished by laboratory analyses alone, of the minute quantity of the samples of water or portion of a single oyster selected for examination, of the transitory and variable conditions represented by each sample at the time of collection, and other similar indeterminate factors which, as pointed out above, are involved in giving to such results a "disease value," it is clear to us why these commissions and official bodies have always laid special stress upon the importance of the "Sanitary Survey" and why for practical purposes, and in order to afford a basis for official action, they have given equal consideration if not precedence to the results of the "Sanitary Survey."

It is, further, quite essential that there should be no misunderstanding as to the magnitude and scope of the engineering field work properly included under the conventional designation of "Sanitary Survey," and to the difficulty of securing without more extended and full series of observations, covering a wide range of physical phenomena, the data to make this survey complete. The velocity and direction of tidal currents under variable conditions of winds; absolute and relative volume of sewage as compared with the fresh water and tidal prisms; ratios of dilution of sewage and tidal water; effects of sedimentation and scour; temperatures and densities of the sewage, fresh water and salt water in relation to stratification; the period of time elapsing during passage of sewage from sewer outfalls to oyster beds or drinking grounds; are all important factors generally embodied in the "Sanitary Survey" which have a direct or indirect bearing upon the problem, and without which an interpretation of analytical results alone would be almost meaningless.

863 It must be evident, then, that an investigation full enough to secure all of the necessary laboratory and engineering data and to satisfactorily solve all of the questions upon which can be based proper and consistent official action relative to the oyster beds and tidal waters in the vicinity of New York and Long Island is a task which it has been impossible to complete in the limited time and with the limited force of laboratory and engineering division assistants available. That a considerable and valuable amount of work has been accomplished by these two divisions along bacteriological and engineering lines, as outlined above, is true, but it is also a fact that, owing to the lack of any provision in the act, under which this investigation was required, to provide the necessary funds to carry out the investigation, it has been performed with no little sacrifice to other important work of the Department;

and that it will be necessary to continue this investigation with a more adequate force of expert assistants, and with more adequate funds, if the problem is to be solved with that definiteness and completeness assumed in the requirements of the act.

What has been accomplished so far is, however, of a permanent character, permanently recorded, and is of such nature as to form a basis of extended and more elaborate work that must inevitably be carried on in the future if rational and consistent official action is to be taken according to the provisions of the act. In the meantime, and pending this further investigation, it is manifestly fitting and desirable that no efforts be relinquished along that course which is not overshadowed by questions or uncertainty and doubt, of remedying or removing any conditions surrounding the oyster beds and waters adjacent to New York bay and Long Island, which may be a direct menace to health or by the removal of which the continued use of any particular oyster bed affected thereby may be more safely permitted.

Power is granted under section 207 of the Forest, Fish and Game Law, whereby criminal action can be taken by you against any one allowing sewage to pollute any oyster bed or beds, and the State Department of Health has also jurisdiction, under the law of 1903, over any additional pollution of the public waters which did not exist at the time the law was passed.

The policy of the State Department of Health since 1905 has been that further and unrestricted pollution of the waters of the State should cease and, insofar as the Department had the
864 power, the existing discharge of raw and ineffectively treated sewage should as rapidly as possible be prohibited.

Active work along these lines has been conducted by the State Department of Health on Long Island since the passage of the law of 1903, and its efforts will be vigorously continued, with the expectation of rapid improvement in existing conditions.

Very respectfully,

EUGENE H. PORTER,
Commissioner of Health.

865 APPENDIX I.

Summary of Pollution Statistics Reported by Sanitary Inspectors, Together with Description of Extent and Character of Shellfish Industry by Districts in New York State, with Results of Sanitary Analyses of Water and Oysters.

Oyster Cultivation Districts in New York State.

1. East Chester and Pelham district.
2. Manhasset bay.
3. Hempstead harbor.
4. Oyster bay district, including Cold Spring harbor and the sound from Matinicock Point to Lloyd Point.

5. Huntington bay and harbor and Northport bay district, including the sound off Eatons Point.
6. Smithtown bay.
7. Port Jefferson harbor district, including sound from Crane Neck Point to Mount Misery Point.
8. Along north shore of Long Island from Mt. Sinai harbor to Orient Point.
9. Peconic bay, Shelter Island sound and Gardiner's bay district.
10. Moriches and Shinnecock bay districts.
11. Great South bay, from Babylon to Patchogue.
12. Hempstead bay, from Far Rockaway to Seaford creek.
13. Jamaica bay.
14. Raritan bay.
(Maps numbered 6, 8-9-10, 13 and 14 are in Appendix III.)

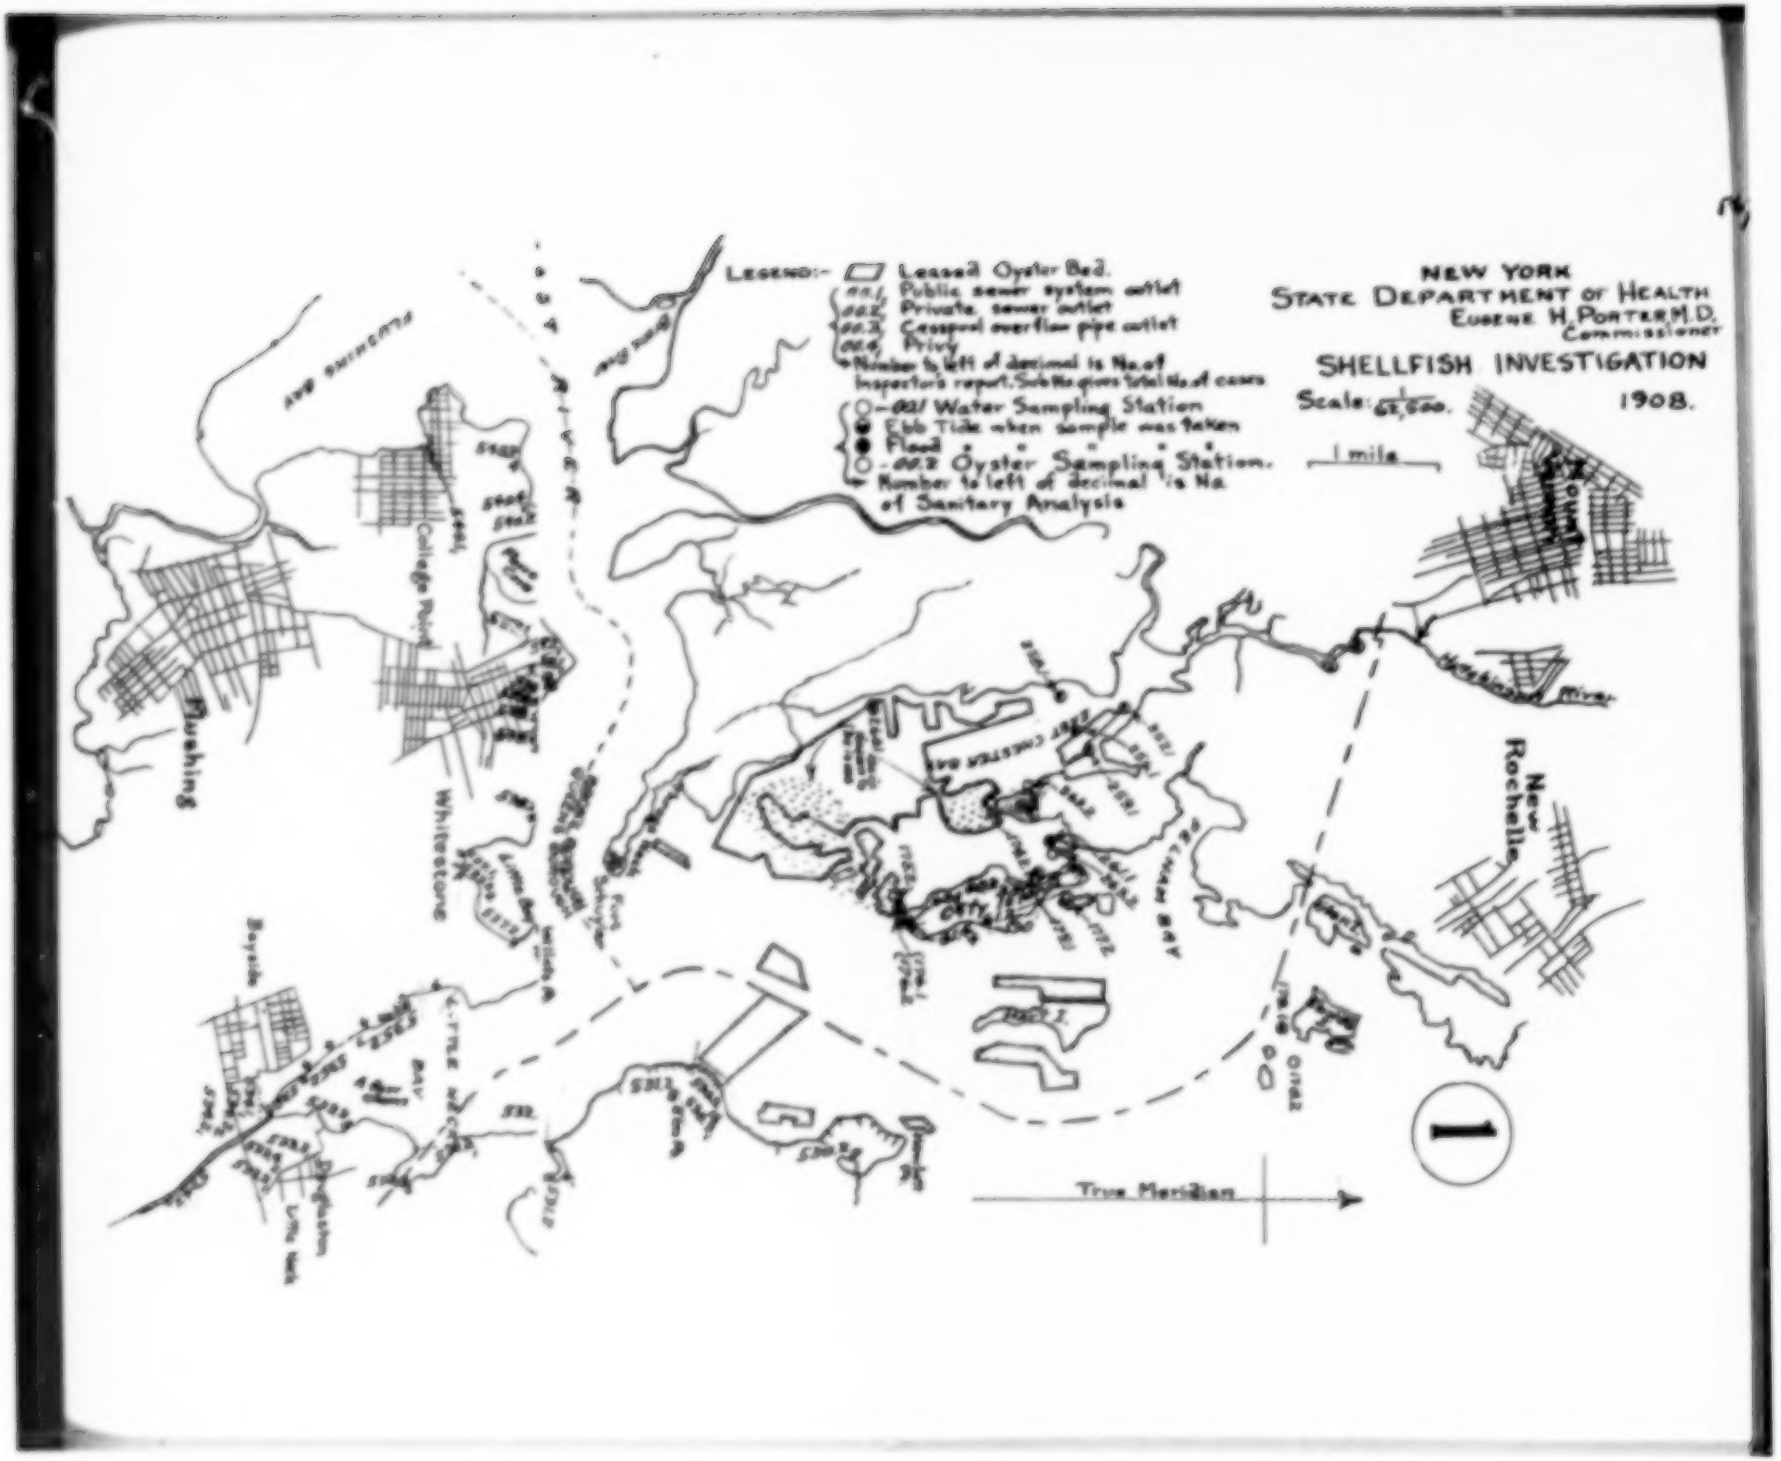
1. East Chester and Pelham Bay District.

This district extends from Throgs Neck and Pelham Bay park on the west to Hart and Davids islands on the east, including the oyster grounds off Elm Point and Hewlett Point on Great Neck, and comprises the head of Long Island sound.

Formerly the greater portion of lower East Chester bay was under cultivated, but mud deposits have greatly interfered with
866 the industry so that the only areas of considerable size that are now planted lie north of Locust Point and south of Rodman Neck.

With respect to tidal conditions it may be noted that the flood tide coming up the East river apparently meets the flood coming up the sound near Throgs Neck, so that it is not likely that sewage from New York city and from the northerly sections of the borough of Queens reaches these beds.

The local pollution consists principally of the sewage discharged into Hutchinson river and canal from the city of Mt. Vernon and the villages of Pelham and Pelham Manor, and of sewage discharged into East Chester bay and the sound from City island.



Sewer systems serving 26,000 persons discharge into Hutchinson river and canal while about 700 persons are served by short individual and party sewers on City island.

From Throgs Neck and Willets Point westerly, considerable sewage is discharged into the sound and into the East river, although, as pointed out, this does not reach the beds under ordinary tidal conditions. From Fort Schuyler on Throgs Neck and Fort Totten on Willets Point, sewage from the garrisons of several hundred men is discharged into the sound. From Whitestone, three main sewer outlets, serving a portion of a population of 3,200 in the locality, discharge into the East river.

At Whitestone, also, twenty-one private sewers discharge into the water, and nine privies were so located as to cause pollution.

At College Point sewage from a population of about 9,000 persons is discharged into the East river.

On Little Neck bay, one semi-public sewer serving thirty houses,

In the tables of analytical data, the sample numbers terminating in .1 are water samples.

Those numbers terminating in .2 are numbers referring to oysters.

The + sign indicates the presence of the B. coli type.

The — sign indicates that the B. coli type was absent.

2. Manhasset Bay.

The only oyster beds under cultivation in this bay lie near Plum Point and Tom Point, about a mile west of Port Washington.

The principal points where pollution occurs are near Port Washington and at the head of the bay.

The pollution consists of discharge from private sewers, overflow from cesspools and from privies located either over the water or near the water.

In the vicinity of Port Washington and in the village, from Barker Point to the southerly limits of the village, nine private sewers and thirteen privies pollute the bay with sewage and wastes from about 200 persons, two of the sewers being hotel sewers.

From the east side of the bay south of Port Washington
868 and from the entire west side of the bay, sewage is discharged from thirty private sewers, while six overflowing cesspools, ten privies and ten households at the time of inspection were polluting the waters. Total population represented is 280.

There are several beds in the sound off shore from Manhasset Neck, from Barker Point to Mott Point. The sewage discharge along this section is very light and consists of six private sewers and two overflowing cesspools.

3. Hempstead Harbor.

This district includes from Mott Point to Weeks Point. The oyster beds are located from Bar Beach, near Glenwood Landing, south, and lie along the harbor a little west of the center. The annual output is about 30,000 bushels. The greatest pollution received by the bay comes from the village of Glen Cove, and reaches the bay through Mosquito Cove about one mile in from the sound. Along the west side of Hempstead harbor from Mott Point to Bar Beach eight private sewers and three privies pollute the waters of the harbor.

Around both sides of the harbor south of Bar Beach, twenty private sewers and twenty-one privies were found to pollute the waters, the greatest concentration being along the ponds in the village of Roslyn. The pollution, therefore, south of Bar Beach, consists of sewage and wastes from about 200 persons, although only half of this is direct.

From Glenwood Landing, opposite Bar Beach, to Weeks Point, including the villages of Sea Cliff and Glen Cove, there are
869 four party sewers serving forty-four houses, although sixteen of these houses discharge wash water only. Also, a sewer from the Ladue leather belting works in Glen Cove takes the sewage from 500 employees.

There are also sixty-three private sewers, two overflows from cesspools, one from a boarding-house property accommodating seventy persons, and seventy-one privies which contribute to the pollution. This gives a total of 955 persons served by sewers discharging directly into the harbor along this section, overflows from cesspools receiving sewage from seventy-five persons and privies so located as to pollute the waters either directly or indirectly, used by 350 persons.

	228.2	....	....	3+1—	....	....

4. Oyster Bay District, Including Cold Spring Harbor and Long Island Sound from Matinicock Point to Lloyd Point.

From Matinicock Point to Lloyd Point, many acres of beds are located for the whole distance along the sound, except at the entrance to Cold Spring harbor. In Oyster Bay harbor the beds lie on three sides of Center island and do not lie so close to the shore of the main land as to Center island. Beds are located entirely across Cold Spring harbor just inside of Rocky Point, and a series of beds lie close to the west side of Cold Spring harbor from Cooper's Bluff southward.

The pollution from Matinicock Point and Dosoris pond to Rocky Point at the entrance to Cold Spring harbor is very slight
870 and is caused by the discharge of seven private sewers and five overflowing cesspools distributed along a stretch of seven or eight miles.

Oyster Bay harbor receives some pollution, there being 250 persons served by forty-nine private sewers discharging into the harbor, twelve overflowing cesspools, and twenty-six privies so located as to cause direct or indirect pollution, so that at present the harbor receives pollution from about 450 persons. The greatest concentration occurs on the creek flowing through the village, there being twenty-one privies polluting this stream besides two private sewers and one overflowing cesspool. The greater portion of this pollution is permanent.

Cold Spring harbor from eighteen private sewers receives sewage from a population of 125 persons, nearly all of which is discharged at the head of the harbor. In addition there are fifteen privies so located as to pollute the waters.

There are extensive oyster beds, mostly for seed oysters located off Llyod Point, the only local pollution being from two privies.

871 5. Huntington Bay and Harbor and Northport Bay District, Including the Sound off Eaton Point.

The oyster beds in this district are located principally in Huntington bay and the northeasterly portion of Northport bay and in the sound northeast and northwest from Eaton Point. A few beds lie in Lloyd harbor, just inside the entrance to Huntington harbor, and a few are located at the entrance to Centerport harbor. There are approximately 200,000 bushels of marketable oysters shipped with barrels from Northport each year, principally to Norwalk and other Connecticut points. Three of the largest seed oyster dealers ship 1,500 bushels per year. No "drinking" is done in this section.

In Lloyd harbor the pollution is caused by two private sewers, serving twenty-eight persons, and a privy at the Lloyd harbor lighthouse, serving five persons.

In Huntington harbor the pollution occurs principally at the head of the harbor, and consists of discharge from twenty-two private sewers serving 220 persons in summer and from 75-100 in winter. Seven of these sewers carry sink drainage only, but the 220 persons stated are served by the remaining fifteen sewers. An 18-inch outlet from the gashouse carries the waste from the process. In addition there are two overflow pipes from cesspools, and three cases of cesspools from which seepage reaches the harbor. One of the direct overflows from a cesspool is at the yacht club. Also seven privies, used by about thirty-five persons, and two house boats directly pollute the waters.

An effort is being made to establish a sewer system in the village of Huntington, and the Huntington Association is carrying on an active campaign to free the waters of the bay and harbor from pollution.

In Huntington bay the discharge from three direct sewers carries sewage from 125 persons. A large summer hotel, with a transit population of from 500–1,000 on special days, is provided with a septic tank and subsoil irrigation system. But at the time of inspection the irrigation system was not properly operated, so that the discharge consisted of septic tank effluent. The pollution of Huntington bay is largely diminished in the fall and winter.

872 On Eaton Point only one privy was found to pollute the waters. Centerport harbor receives sewage contributed by thirty persons through three private sewers. In addition, three sink drains serving a population of 140 persons, and two overhanging privies pollute the waters. This discharge is almost entirely at the head of the harbor.

Northport bay receives sewage pollution from 1,300 persons through thirty-seven private sewers, and two public sewers. In winter this estimate is reduced somewhat, and in summer the sewage from the 525 pupils and teachers in the public school included in the estimate does not reach the bay. In addition, one cesspool, receiving sewage from ten persons in summer only, overflows into the bay, and seven overhanging privies directly pollute the water.

The greater portion of sewage discharged into Northport harbor comes from the village.

	269.2	....	....	1+5—	0+6—	....

873 6. Smithtown Bay.

In Smithtown bay, extensive oyster beds are located from about three-eighths of a mile to a mile off shore west of the Nissequogue river, while east of this river the beds lie close to the shore, commencing a half mile east of the river and extending for over two miles. Practically no pollution of the waters of the sound occurs except near the Nissequogue river.

At East Beach near Northport bay, one direct sewer and one privy pollute the waters.

A short distance west of the Nissequogue river the main sewer from the Kings Park Hospital discharges, carrying sewage from 4,000 inmates and attendants. The nearest beds lie, as previously mentioned, about one-half mile from this sewer and from the mouth of the Nissequogue river.

At the mouth of the Nissequogue river, a sewer from the laundry at the Kings Park Hospital, carrying laundry waste only, discharges.

The Nissequogue river is polluted by sewage from eight private sewers serving a population of seventy-five persons, by seven sink drains, by one overflow from a cesspool and by three privies, the greater amount of this pollution being discharged into the head waters of the river.

Through Porpoise channel and Stony Brook harbor, Smithtown bay receives pollution at the extreme eastern end by discharge of sewage into the above-named waters from seven sewers, serving sixty-three persons. Fourteen sink drains and eleven privies also pollute the waters of Porpoise channel and Stony Brook harbor.

The nearest oyster beds to the outlet of Porpoise channel lie three-quarter mile to the west and one-quarter mile off shore.

874 7. Port Jefferson Harbor District, Including the Sound from Crane Neck Point to Mt. Misery Point.

The oyster beds in this district lie along the sound shore and in the central portion of Port Jefferson harbor. Practically no pollution of the sound exists except one direct outlet into Flax pond serving five persons, and one sink drain, at Oldfield Point. Into Conscience bay, five direct outlets discharge, serving a population of thirty persons, while four overhanging privies pollute the bay.

The pollution of the westerly portion of Port Jefferson harbor adjoining Setauket beach and the village of East Setauket consists of sewage discharged through twelve private sewers serving seventy-five persons. There are also three sink drains which discharge into this section. Only four of these private sewers are near oyster beds.

The pollution which reaches the easterly section of Port Jefferson harbor comes from the village of Port Jefferson at the head of the harbor, one-half mile from the nearest oyster beds, and consists of sewage discharged from twenty-five direct sewers leading to the main creek, which serve as sewers for a population of 300 persons.

Of the twenty-five direct sewers, five are from hotels. In addition, twelve sink drains discharge into this creek.

Along this stream ten overhanging privies cause pollution of the waters, and two livery stables drain washings into the stream.

On the southeasterly portion of the harbor, twelve overhanging privies discharge into the water, and on the westerly side of the harbor, three direct sewers, one sink drain and four overhanging privies, all within the village, pollute the waters. The total pollution of the harbor, therefore, from Port Jefferson village is represented by the sewage and waste from 450 persons, and is fairly constant throughout the year.

(Here follow Exhibits marked No. 6 and 7.)

8. Along North Shore of Long Island from Mt. Sinai Harbor to Orient Point.

There are only two small groups of beds in this district. One of these groups lies off Hashamomuck beach and extends from a mile to two and one-half miles east of Horton Point. The other group lies between Rocky Point and Terry Point opposite Orient harbor. Some oystering is carried on in Mattituck inlet.

Application has been made to the Marine Fisheries Bureau for oyster grounds in much of this section but such grounds are not in use, the lease having been granted subject to examination for natural growth.

Four hundred and fifty bushels of oysters per year are shipped from Mattituck.

The pollution is inconsiderable along the entire sound front.

In Mt. Sinai harbor, six sink drains discharge at various points and three overhanging privies pollute the waters at points remote from oyster beds.

Three overhanging privies pollute the waters of Wading river.

At Waterville on Mattituck inlet one drain from sinks and urinals at a hotel and one overhanging privy discharge into the inlet.

About one-half mile east of Horton Point, two cesspools receiving sewage from seventeen persons overflow into the sound, and between this point and Inlet point there is one private sewer serving nine persons.

876 At Truman Beach, one private sewer discharges one-quarter mile from the oyster beds, and at the west end of the beach, at St. Thomas summer recreation home accommodating 120 children at a time, kitchen wastes only are discharged into the sound.

	330.2	.....	.....	4+2—	.....	.....

9. The Peconic Bays, Shelter Island Sound and Gardiners Bay.

This district comprises the arm of the ocean included between the two easterly peninsulas of Long Island.

The beds in these waters are leased by the oyster commissioners of the county of Suffolk. Leased oyster beds occupy the greater portion of the bottoms of the bays, the only lands not leased lying under the central portions of Great Peconic bay and Little Peconic bay, nearly all of Noyack bay, the central portion of Gardiners bay and narrow strips along the shores of the bays, which are held as natural beds. Seed oysters, principally, are taken from the beds in this district.

The principal points from which these waters receive pollution are

Riverhead, Greenport, Shelter Island Heights, and the Manhanset house on Shelter Island, and Sag Harbor on the south shore of Shelter Island sound.

At Riverhead, two public sewers and one private sewer discharge sewage from a maximum of 475 persons, although this number probably falls to about 300 after the summer season. Along the Peconic river as it passes through Riverhead and the immediate vicinity, fifteen privies are so located as to pollute the stream
877 to some extent. The overflow from one cesspool reaches the waters of Flanders bay.

The oyster beds nearest Riverhead lie opposite the village of South Jamesport, four and one-half miles from the village of Riverhead.

From South Jamesport along the northwesterly shores of the Peconic bays and Shelter Island sound to the village of Greenport, very little pollution is added to the waters. Two miles east of South Jamesport one cesspool overflow pipe discharges into Great Peconic bay at a point about a mile distant from the leased beds. At New Suffolk, two cesspool overflow pipes and one sink drain discharge into the bay during the summer months.

The Standard Oyster Company at New Suffolk ship about 1,000 bushels a day during a portion of the season.

At Southold, two sink drains and one private sewer discharge into an arm of Southold bay.

Near Conkling Point a privy at a brickyard discharges on ground flooded at high tide.

At the village of Greenport, west of Fanning Point, two private sewers, serving nineteen persons, discharge into Pipes cove. From Fanning Point to the railroad dock six private sewers serving thirty persons discharge into Greenport harbor. A public sewer, with several laterals, discharges at the end of the ferry slip at the foot of Main street in the village of Greenport. The maximum number of persons served by this sewer system is 1,580, and varies somewhat since a school building, accommodating 600 pupils, is connected, as well as three hotels having a combined guest capacity of 130. Six overhanging privies pollute the waters at the shipyards along the water front.

Four party sewers, serving a population of 250–280, discharge into Stirling basin.

There is but one oyster-house in Greenport, and from 45,000 to 60,000 bushels per year are shipped from this house. "Drinking" at this house is done in private ponds of spring water.

Opposite Conkling Point and Greenport, Shelter Island sound receives sewage from Shelter Island as follows:

At Jennings Point, and south of Jennings Point, Shelter
878 Island sound receives sewage from thirteen private sewers serving sixty-five persons. These are mostly from summer cottages.

From Shelter Island heights the association sewer discharges at a point 500 feet from shore, and the maximum number of persons served by this sewer during the summer months is 1,050. This

number is largely reduced after the summer season. In addition, three private sewers, serving seventeen persons, discharge into Derring harbor.

The Manhanset House sewer, serving as a maximum 570 guests and attendants, discharges under the steamboat dock 200 feet out from shore.

On the east side of Derring harbor, the sewage from twenty-three cottages is discharged into two large cesspools having overflow pipes reaching seventy-five to one hundred feet into the harbor. This represents a discharge of sewage, or cesspool overflow, from 115 persons during the summer months.

Orient harbor receives sewage at points remote from oyster beds from three private sewers serving fifteen persons and one sewer serving fifteen persons and one sewer from a hotel having 100 guests.

A boarding-house near Long Beach bay discharges sewage into the bay.

Along the south shore of the Peconic bay, Noyack bay and Shelter Island sound very little sewage is discharged into the waters, except at Sag Harbor. One cesspool with an overflow pipe discharges into Little Peconic bay at Nyack.

At Sag Harbor, two public sewers and two private sewers discharge sewage from 715 persons into Shelter Island sound inside the breakwater. The above number includes the employees at a watch case factory and a maximum guest capacity of three hotels.

At North Haven, a private sewer discharges into the sound, and from the south shore of Shelter Island, three private sewers, serving fifteen persons, discharge into swamps and bay.

10. Moriches and Shinnecock Bays.

No oystering on a commercial scale is done in these waters. Moriches bay is in general too shallow for oyster culture. There are no leased or cultivated grounds in Shinnecock bay, although many natural beds are found in both the east and west portions of this bay. A few natural growth oysters are found in Mecox bay, also.

Some pollution of the waters occurs around Moriches bay. One cesspool overflows into Forge river. Five cesspool overflow pipes discharge into the bay and tributary streams east of Masury Point, two of these leading from boarding-house properties or hotels. At West Cove, one direct sewer from a cottage, and one overflow pipe from a cesspool from a summer hotel having a capacity of 100 guests discharge into the water. At Hart's Cove the overflow from a cesspool at a hotel having a capacity of eighty persons discharge into the water, as well as the overflow from a cesspool at a summer school accommodating 250 persons.

Duck farms on Terrell river, Hart's Cove, and on Seatuck creek pollute the waters.

One private sewer and one cesspool overflow pipe discharge
880 into Seatuck creek. There are also duck ranches on Speonk river and at Tanner Neck. Practically no pollution of the waters occurs from this point eastward along the shores of Long Island to Montauk Point.

Oyster Cultivation District No. 10.

Moriches and Shinnecock Bay District.

No samples taken.

11. Great South Bay from Babylon to Patchogue.

The principal sections of Great South bay in which oysters are cultivated on leased lands lie from a point opposite Bay Shore for a distance of ten miles eastwardly to Bayport. A few beds are cultivated in the vicinity of Oak Island. From Nichols Point westward the beds in this district are leased by the oyster commissioners of the town of Islip. From Nichols Point eastward to Bayport, including portions of the bay which lie in the town of Islip, and portions which lie in the town of Brookhaven, the beds are leased by the heirs of the Smith estate. Easterly from this point, in the town of Brookhaven, no beds are leased by the town, but much natural growth occurs in the vicinity of Patchogue. Areas are leased by the oyster commissioners of the town of Brookhaven on the bay front at Patchogue, for the purpose of storing oysters for the winter market. The oyster grounds in Great South bay are maturing grounds and furnish the famous Blue Point oyster.

The principal shipping points are at Bay Shore, West Sayville,

Sayville and Patchogue. In a normal year over 700,000 bushels are shipped from the first three points named. From one-third to one-half of these oysters are opened at the houses.

There are no public sewer systems discharging into Great South bay. Some slight pollution of the westerly portion of the bay and its tributary streams occurs along the shore from Amityville to Bay Shore. The principal pollution along this district occurs at Babylon where a party sewer serves one hotel and six houses.

At Bay Shore, Penataquit creek, at the mouth of which are located three oyster-houses, receives pollution from four
881 private sewers, eighteen overflow pipes from cesspools and twelve privies, Bay Shore creek receives pollution from ten cesspool overflow pipes and six privies. Four cesspool pipes in each case discharge into Great cove and Champlin creek. Nichols bay and the Connetquot river receive pollution from six overflow pipes from cesspools.

At West Sayville no direct pollution occurs.

Opposite Sayville three overflowing cesspools discharge directly onto the beach or into the bay. Along the west side of Browns creek eight privies are so located on marsh land that some pollution at extremely high tide is possible. One cesspool discharges into this creek. At Browns Point four privies are located on land subject to overflow at ordinary high tide. One of these adjoins an oyster float basin and undoubtedly pollutes the water.

From the shore opposite Bayport and Blue Point, two private sewers and four cesspool overflow pipes pollute the bay.

Patchogue creek receives considerable pollution. A main sewer which drains the business portion of the village receives sewage from two hotels and about forty houses. A sewer from the lace mill discharges direct and receives sewage from 150 of the employees, while the sewage from 350 of the employees passes through cesspools. Manufacturing waste from this mill is also discharged into the creek. A sewer from a lumber yard discharges sewage from 200 employees. Two hotels discharge cesspool overflow into the bay, and one hotel, having a capacity of 200 guests, discharges sewage directly into the bay. Cesspools at the Patchogue Yacht Club overflow into the bay. In addition, four private sewers, and four overflow pipes from cesspools at individual houses contribute pollution to the bay.

Patchogue bay, therefore, is polluted either directly or indirectly by sewage from a population of nearly 1,500 persons.

The pollution of Great South bay, from Patchogue eastward, is inconsiderable.

(Here follows Exhibit marked No. 11.)

12. Hempstead Bay from Far Rockaway to Seaford Creek.

This district includes all the bays and creeks inside the ocean beach opposite the town of Hempstead. The oyster beds are located along the deeper channels over the greater portion of this area.

At the extreme westerly end of the district, oysters are cultivated in the upper reaches of broad channel and in the tributary leads and channels. In the easterly section, the beds are found in various channels from Cinder creek and Middle bay east to Great Island channel.

The oyster grounds in this district are maturing grounds, and the principal shipping points are at Woodmere, East Rockaway, Milburn and Freeport.

The pollution consists of discharge from private and party sewers from overflowing cesspools and from privies. No public sewer systems discharge into the waters of Hempstead bay.

East of the village of Far Rockaway, Bannister creek receives sewage from fifteen cottages through a party sewer, from two private sewers and from eight overflow pipes from cesspools, and the total population represented being 125.

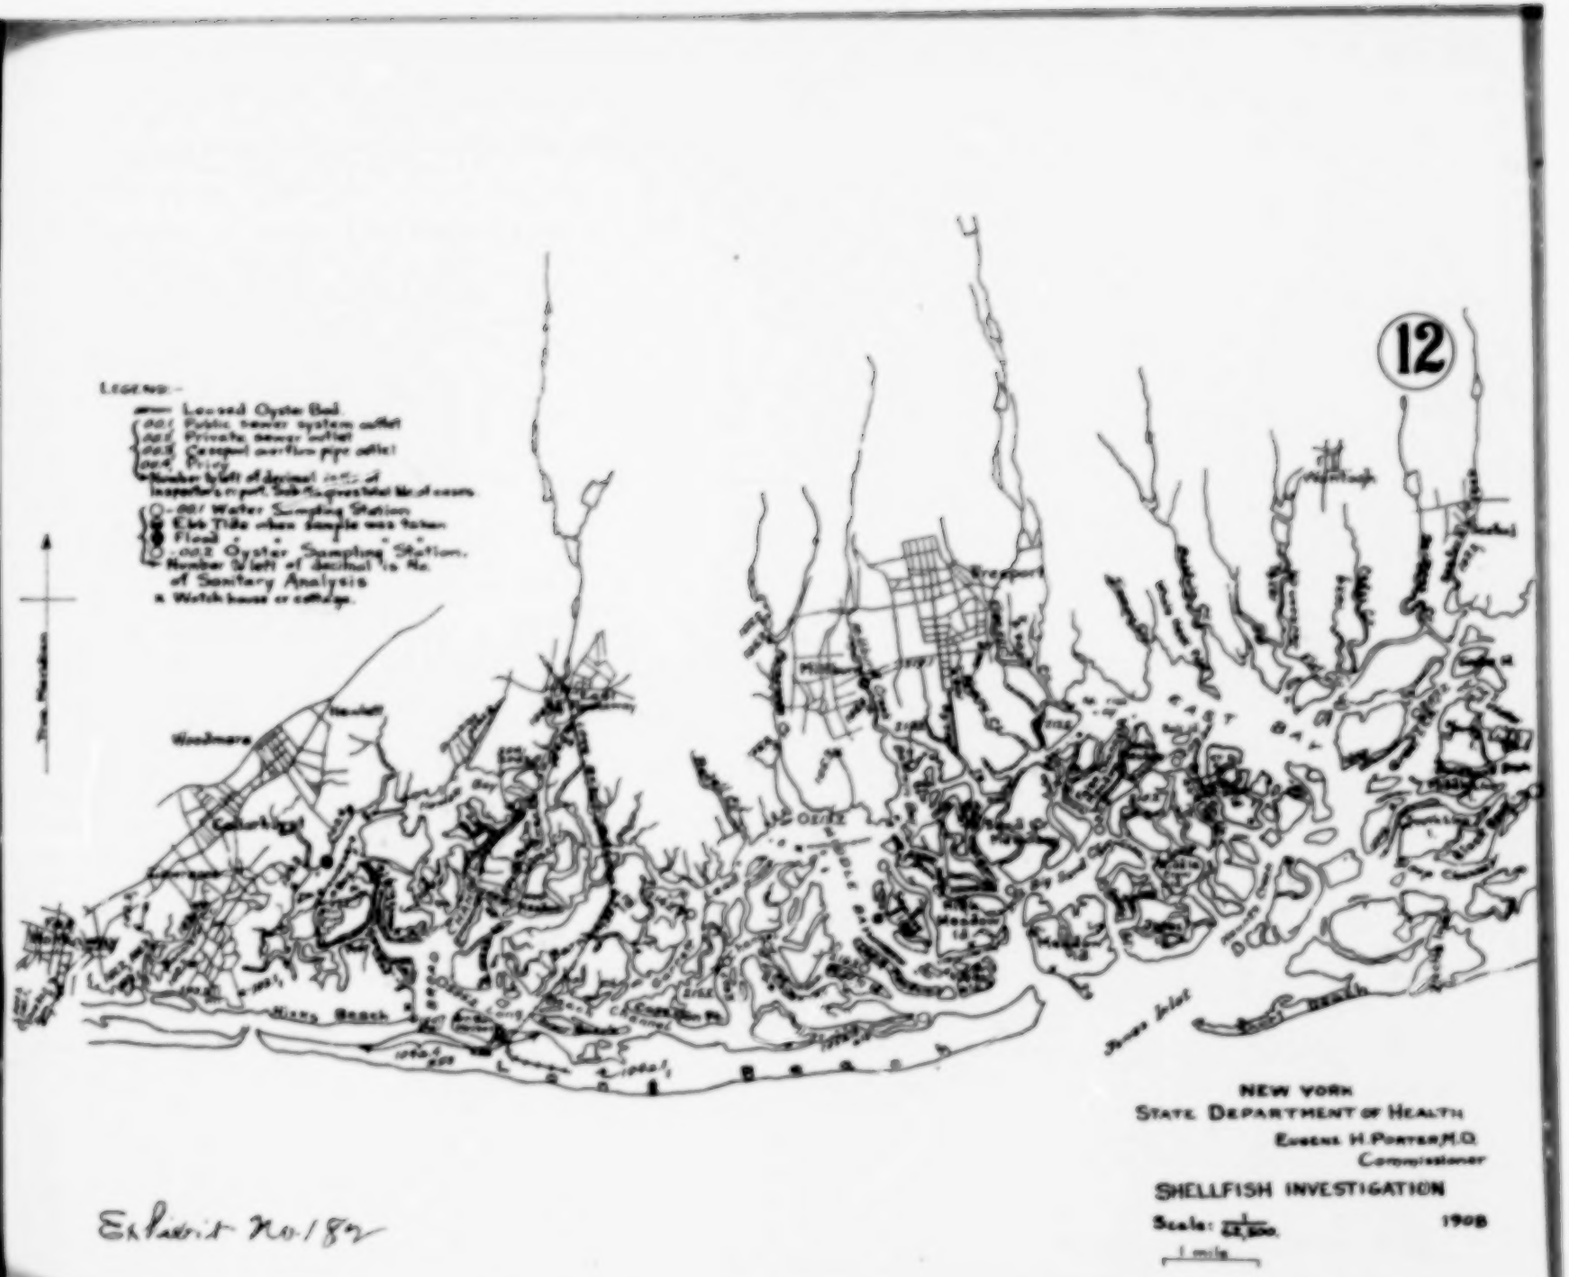
883 At the westerly end of Hick's beach, nineteen cottages are served by a party sewer. Brosewere bay receives the overflow from the cesspool at the Rockaway Hunting Club, and in addition eight cottages have privies discharging into the water.

At East Rockaway, three private sewers discharge into the creek and six privies are so situated as to possibly cause pollution of the waters.

At Long Beach, a sewer serving twenty cottages or 100 persons, discharges in the summer season on to the marshes and may cause some pollution of the waters. About fifty privies along this beach are so situated that some pollution of the waters of Broad channel might result.

In addition, two privies are located along Broad channel, two along Post Lead and ten on Blackbank Hassock.

The foregoing comprises a statement of all the pollution which might affect the oyster beds in the westerly portion of Hempstead bay.



There are about twelve or fourteen oyster dealers at Woodmere dock, and shipments from this point may reach 15,000 to 20,000 bushels per year. About eight oyster-houses are located at East Rockaway. It is estimated that about 40,000 bushels per year are shipped from the grounds in Hempstead bay, west of the Long Beach railroad.

The drinking places in this section are at Hewlett creek and in two streams at East Rockaway.

At Hewlett creek, no pollution occurs in the immediate neighborhood of the drinking places.

At the main stream in East Rockaway, eight houses are located and very little pollution of the stream occurs.

A branch creek to the east of the village on which is located one oyster-house at which drinking is done is polluted by two privies

upstream from the house, one discharging directly. Also, two privies a short distance downstream pollute the waters.

The easterly section of Hempstead bay receives comparatively little pollution.

The three streams near Milburn are polluted by discharge from one private sewer, five overflow pipes from cesspools and five privies, representing a population of about fifty persons. The nearest oyster beds are a mile to the south in Middle bay.

884 At Freeport no direct sewage discharge occurs.

The only pollution of the waters is from one cesspool overflow and twelve privies on the three streams near the village. The pollution of Hempstead bay from this point eastward is also very slight. On Jackson creek are located two privies. On Cedar creek, one privy is located and Seaford creek receives sewage from one private sewer.

In addition to the pollution thus far noted, the easterly portion of Hempstead bay receives pollution from fifteen privies at Nassau-by-the-Sea near Point Lookout L. S. Station, and from privies at watchhouses and cottages located near oyster beds at the following points: One along Scow creek, one along Cinder creek, three on Alder and High Meadow islands, five adjacent to Long creek, one or two near False channel and Neds meadow, five along Broad channel, none direct, five along Great Island channel, three along South Line Island channel.

The drinking places along this section of Hempstead bay are at Milburn creek and Freeport creek and only very slight pollution from two doubtful privies in each case is possible. About 80,000 bushels of oysters per year are shipped from this section, making the total output from Hempstead bay about 120,000 bushels per year.

(Here follows Exhibit marked No. 12.)

885 13. Jamaica Bay (Brief Statement of Conditions).

The oyster beds in Jamaica bay, which is the largest oystering district in New York State waters, are leased by the State. Nearly every portion of the bay is occupied to some extent by oyster beds, although the industry is carried on most extensively west of the Rockaway Beach railroad. The maps accompanying this report show the location of all beds leased by the State in Jamaica bay. There are many beds shown on the maps including some near Rockaway Beach and the northeasterly end of Big channel that are not being used for oyster cultivation at the present time.

The principal shipping points on Jamaica bay are at Canarsie, Inwood and near Flatbush bay, although the greater portion of the trade is handled by schooners going directly from the beds to the New York market.

The yield of market oysters from Jamaica bay probably ranges from 500,000 to 1,000,000 bushels yearly.

The principal points of pollution are at the four sewage disposal plants at Sheepshead Bay, East New York, Jamaica and Far Rockaway, at the outlet of the Paerdegat and Kings county hospital sewers into Paedegat basin, at Bergen Beach, at Canarsie and along Rockaway Beach district. In addition to these points pollution reaches the bay from various summer cottage colonies, the principal colonies being located at Plum Beach, at Sand Bay, east of Canarsie, along Mill creek, at Ramblersville or Remsen Landing, along Bergen and Cornell creeks, and at the several stations on the bay of the Rockaway Beach railroad.

The pollution differs greatly at most points in the summer and winter seasons. The Sheepshead Bay disposal plant, using the chemical precipitation method, which the other three plants also use, receives sewage from a normal population of 2,000 in winter to a summer population of 40,000 to 50,000 on special days. The treatment is practically ineffective.

Bergen Beach is visited by from 50,000 to 60,000 persons weekly in summer, and the sewage, from an average of 8,000 persons daily, is discharged into the bay.

Paerdegat basin receives sewage from a permanent population of over 10,000 persons.

886 Canarsie is visited by an average of 16,000 persons daily in the summer season, including 30,000 on Sundays, and practically all the sewage from this population reaches the bay.

A permanent population of considerably over 50,000 persons contribute sewage to the New Lotts or East New York disposal plant. An average of 10,000,000 gallons of sewage and storm water per day is pumped at this plant, and in addition a relief by-pass is in operation from eleven o'clock a. m. until midnight. The plant is so much overtaxed, the sewage being detained for only seventeen to twenty minutes, that the treatment is practically ineffective.

At Sand Bay, 127 cottages, at Old Mill creek, 176 cottages, at Ramblersville, 220 cottages, at Bergen creek, 50 cottages, at Cornell

creek, 53 cottages, and along the line of the Rockaway Beach railroad over 200 cottages have privies which discharge into the water or onto marshes subject to tidal overflow.

The Jamaica disposal plant, effluent from which is discharged into a branch of Bergen creek, treats the sewage from about 18,000 persons out of a total population of 25,000 in Jamaica. The plant has ample capacity as a chemical precip-ation plant, although, under the best of operating conditions, a reduction of organic matter and bacteria of about 50 per cent. only is possible.

The Far Rockaway disposal plant receives sewage from a normal population of 6,500 and a summer population of 30,000. During the summer season, the plant is undoubtedly overtaxed.

The Rockaway Beach district varies greatly in population. In the winter season, from October to June, the population is about 6,000 as based on the registration. During the summer season the average daily population is from 55,000 to 60,000, and on a conservative estimate, based on the traffic figures of the railroad and steamboat lines carrying passengers to this district, the population in this district on certain days may reach as high as 125,000 to 150,000.

Twenty-nine public sewers discharge sewage from this varying population directly into Jamaica bay.

889 14. Raritan Bay (Brief Statement of Conditions).

Oyster grounds in Raritan bay are leased by the State. The beds are principally located from Great Kills west to Tottenville and reach nearluy half across the bay. West of Seguine Point, it is stated, the beds are used as propagating ground and no oysters are taken to be marketed from these beds.

The annual output from beds in Raritan bay, is estimated to be from 450,000 to 500,000 bushels and is sold principally in the New York market.

It is generally stated that the ebb tide coming out of the Narrows and swinging toward Raritan bay meets the ebb from Raritan bay at points to the northeast of Elm Tree beacon, so that the sewage discharged from New York city does not under ordinary conditions pass over the oyster grounds in Raritan bay during ebb tide.

Briefly, the sewage pollution of Raritan bay is as follows:

At Tottenville a population of 2,000 is served by a public sewer system having four outlets into Arthur Kill and Raritan bay.

From Ward Point to Red Bank, nine private sewers and one privy pollute the waters.

At Red Bank, a Catholic mission with 2,000 inmates discharges sewage directly into the bay.

At Seguine Point, a dental goods manufacturing company, employing 600 hands, discharges all sewage directly into the bay.

There are also three private sewers serving ten houses, and two privies on Princess bay and Lemon creek which pollute the waters directly.

East of Seguine Point, a large hotel with a capacity of 200 has practically a direct sewer to the bay. Three private sewers and one cesspool overflow also pollute the waters of the bay near Latourette pond. A short distance west of Great Kills, three private sewers discharge into the bay. At Great Kills one hotel discharges into a small stream and one discharges direct. Three other private sewers and two privies pollute the waters of Great Kills.

West of Midland Beach, a hospital with 300 inmates and attendants discharges sewage directly into the bay as well as a hotel with a capacity of fifty.

890 At Midland Beach, all the sewage is discharged into trenches in the meadows just back of the resort. Three hotels and a number of cottages are connected to the main sewer. This is a large summer resort and undoubtedly some of the sewage would reach the bay.

At South Beach, sewage from a summer resort visited by 1,000 persons a week is discharged directly into the bay.

Pollution Reaching Raritan Bay from New Jersey Municipalities.

The Raritan river in New Jersey receives considerable sewage pollution, the description of which follows:

At its mouth, approximately one-third of the sewage from 27,000 persons at Perth Amboy is discharged into the Raritan, and the rest into Arthur Kill. South river, a tributary of the Raritan, receives pollution from sixty-five private houses.

New Brunswick, population 23,000, discharges sewage direct but is under notice from the New Jersey State Board of Health to cease polluting the river by July, 1911.

Highland Park, population 714, discharges direct but will be required to treat sewage by July, 1911.

Bound Brook, population 4,000, and New Bound Brook, population 1,000, both discharge sewage direct, but are under orders to cease such discharge by July, 1911.

Somerville, population 5,000, discharges directly, but is to treat sewage by July 1, 1911.

Raritan, population 3,500, discharges directly.

Flemington has a septic tank and sand filters and takes water at Flemington Junction with no filtration. No considerable pollution occurs on Millstone river.

Green brook, a tributary stream to Bound brook and the Raritan, receives sewage directly from Lincoln, population 300.

At Plainfield, septic tank and secondary contact bed treatment are in use.

The Rahway river, discharging into Arthur Kill about eight miles from Raritan bay, receives sewage from Rahway, population 8,650, and Cranford, population 3,600. Both these boroughs must cease polluting the river by November 11, 1911.

891 Below Rahway, the State reformatory with 1,000 inmates discharges sewage into a septic tank and the effluent after passing over mud flats reaches the Rahway river. Plans to install sand filters are under way.

The Orange joint trunk sewer discharging into Arthur Kil. serves a population of 25,000 to 30,000, and Elizabeth, population 60,000, discharges most of its sewage into Arthur Kill.

Roselle has population of 1,300 connected with sewage discharging into Morse creek, a tributary of Arthur Kill.

The town of Linden has twelve private sewers discharging into West brook.

The Shrewsbury river receives pollution by direct sewage discharge as follows: Sea Bright, population 1,160, has 200 private sewers, some hotel sewers and some joint or party sewers.

Red Bank, population 6,260, has septic tank and filters.

Atlantic Highlands, population 1,480 in winter and 2,000 in summer, discharges sewage direct into Raritan bay, but is to build septic tank by June 1, 1909.

The Waterwitch Club, population 1,000 in summer, have septic tank completed in August, 1908, and sand filters were to be installed during the fall of 1908.

1 COMPLAINANTS' EXHIBIT No. 183. James D. Maher, Commissioner.

Joseph A. Deghuée, Ph. D.
Frederic D. Bell.
Harry E. Bramley.
Herbert D. Pease, M. D.

Lederle Laboratories,
39-41 West 38th Street, New York City.

No. —.

Directions for Collecting Oysters for Bacteriological Examinations.

Select twelve (12) or more oysters, preferably three or more years old, from each bed to be tested.

Pack the twelve (12) or more oysters from each bed in the shell in a paper ice-cream or bulk oyster box.

Mark each box with the bed number.

Fill out information blank, put in envelope and attach to box containing corresponding bed sample.

Pack paper boxes containing oysters in wooden box with excelsior.

Ship samples by express as soon as possible after collection. Do not lay down or float oysters before shipment or allow them to come in contact with dirt or other material.

If the sample is to arrive at the laboratory within thirty-six (36) hours during the winter season no ice is necessary. Ice is not necessary if sample is to arrive within twenty-four (24) hours at any season.

Directions for Collecting Water for Bacteriological Examinations.

The utmost care must be taken that the fingers do not come in immediate contact with the stopper or neck of the bottle. Loosen the edges of the tinfoil from the neck of the bottle. Grasp the stopper, still covered by the tinfoil, in the left hand and the bottle below the neck with the right and gently remove the stopper. If the latter sticks it can be loosened by a slight tap on the edge of the stopper.

Under no condition should the part of the stopper not covered with tinfoil, be allowed to come in contact with anything.

Plunge the bottle rapidly below the surface to avoid surface scum; get it completely full and withdraw quickly.

If the sample is taken from a shallow source, avoid disturbing the sediment at edges or bottom.

Empty out a small portion of the water, so as to leave a small

space in the bottle for expansion. Return the stopper and press the edges of the tinfoil around the neck of the bottle.

Place in the mailing case. The shipping case contains sawdust. This box should be filled with cracked ice mixed with the sawdust and the cover put on tightly.

The shortest possible time should elapse between sampling and shipping by express.

2 Lab. No. —. Section No. —. Bed No. —.

Information Relating to Sample of Oysters Submitted for Analysis.

(To be filled in by person taking samples.)

Date of Collection, —— —, ——.
Collected by, —— ——.
Description of source, ——.
General location of bed, ——.
Hour of Collection, ——.

(Give name of bay, harbor, cove, pond, river or creek in which bed lies and name of town in case of an inside bed.)

Official designation of bed including number, etc. ——.
Give distance from nearest point on shore or from light-house or charted buoy and state compass direction from locating point. ——.
State whether bed lies near mouth of a river or creek. ——.
Depth of water over bed, ——.
Kind of bottom—hard or soft, ——.
Wind—direction, ——.
Tide, ——.
Sand, Clay or Mud, ——.
Velocity—strong or light, ——.
Weather, ——.

After filing out blank, place in envelope and attach to box containing oysters from corresponding bed.

1 COMPLAINANTS' EX. No. 195. James D. Maher, Commissioner.

Weekly Report to Dr. H. D. Pennypacker Lederle Laboratories, on Sanitary Inspection of South Shore of Staten Island for Sealshipt Oyster System, Inc.

In order to locate private sewer outlets on the south shore of Staten Island between South Beach and Tottenville, I visited the Department of Public Works at Borough Hall, St. George, S. I. There are no maps in the Department showing these private sewer outlets.

Outlets of public sewerage system at Tottenville obtained.

In order to bring up to date locations of sewer outlets given in 1908, report of N. Y. State Board of Health, I began a sanitary inspection of the above shore.

The results of these inspections are given on following pages.

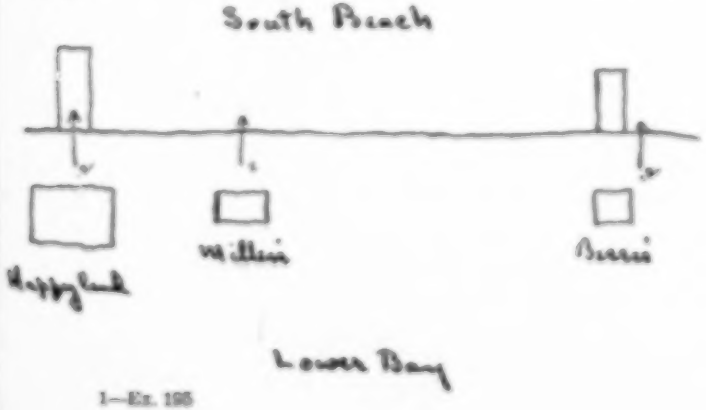
July 1st, 1910.

2 June 20, 1910.

South Beach, S. I.

There are three (3) sewers along this beach discharging into the lower bay, the outlets being located just beyond low water mark.

1. In front of Happyland entrance, 6" iron pipe, under pier, outlet 50' beyond low water mark.



2. In front of Miller's Hotel small sewer discharges under pile of rocks 20' beyond low water mark.

3. In front of Bessi's Hotel small sewer discharges under pile of rocks about 20' beyond low water mark.

Most of the hotels and cottages have cesspools or privies. These do not directly pollute the bay and the polluting matter is probably pretty thoroughly filtered out before the bay is reached.

There are bathing beaches along this whole shore front.

Up to the present time comparatively few people have visited the resort.

3 June 21, 1910.

Visited Metropolitan Sewerage Commission of New York #17 Battery Place. Dr. Soper out. Copied Raritan Bay records of Commission.

Float Records.

Courses of floats started in the Upper Bay, or in the Hudson or East Rivers and passing out through the Narrows.

Year 1907:

Out of 12 floats passing out through the Narrows on ebb tides—
8 took a course through the Main Ship Channel East of the Hoffman and Swinburne Islands and east of West Bank light.
2 passed out along the Coney Island Channel,
2 passed to the West as far as South Beach only—
Of these one grounded on the beach, the other returned on the next tide to the Narrows.

Year 1908:

Out of the three floats passing out through the Narrows on ebb tides—
1 passed along the Main Ship Channel east of Hoffman Island
1 " " " " Coney Island Channel,
1 went to the westward as far as South Beach only.

Year 1909:

Out of 5 floats passing out through the Narrows on ebb tides—
2 passed out through Ambrose Channel
2 passed out through Coney Island Channel
1 passed out through Main Ship Channel.
There is no record of any float passing from the Narrows to the Raritan Bay Oyster grounds.

Conclusion: The courses of floats, as observed by the Metropolitan Sewerage Commission in 1907, 1908 and 1909 would indicate that the Raritan Bay oyster grounds are not directly polluted by
4 New York sewage.

Copy of Records of Water Analyses of Raritan Bay Made by Metropolitan Sewerage Commission in 1909.

This commission did not regard the presumptive or lactose bile test as sufficient evidence of the presence of B. Coli in the water and decided that it was not practicable to carry out the isolation tests in each case.

They based their conclusions as to the pollution of the water at various points on the bacteria count and the percentage of dissolved oxygen saturation, combined with the results of the sanitary inspection.

The bacteria were plated out as soon as collected on the boat, on standard gelatin and grown for 48 hours. The dissolved oxygen determinations were also made on the boat as soon as the sample was collected, the A. Levy method being used.

4433

7 June 21, 1910.

The 1906 report of the Metropolitan Sewerage Commission states that the oyster beds in New York bay are almost exclusively located on the southeast side of Staten Island and Gravesend Bay beyond the Narrows and concludes that most of the oyster and clam beds are free from dangerous pollutions, although there are some on the Staten Island shore near the narrows and the Kill von Kull and some in Gravesend Bay, which are nearer sewer outfalls than is proper.

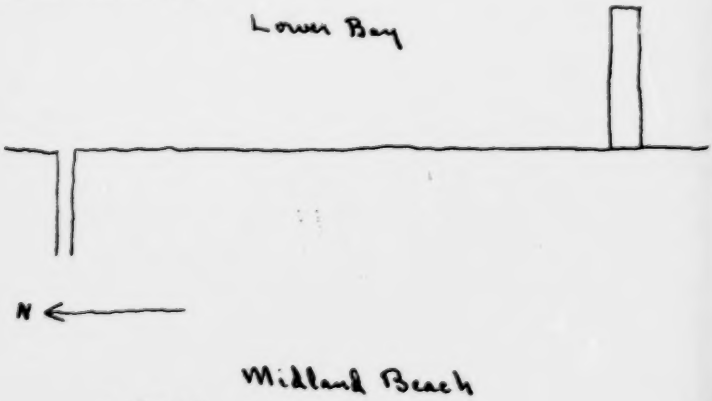
The results of the bacteria and dissolved oxygen tests made by the same commission in 1909 confirm the above conclusion regarding the condition of the Raritan Bay oyster beds at the present time.

The beds were not dangerously polluted at points where the samples were taken but no samples were taken at points close to the private sewer outfalls or inside the Great Kills, where the pollution is probably greater.

It is generally stated that the ebb tide coming out of the Narrows and swinging toward Raritan Bay meets the ebb from Raritan Bay at points to the northeast of Elm Tree beacon, so that the sewage discharged from New York City does not under ordinary conditions pass over the oyster grounds in Raritan Bay during ebb tide.

8 June 22, 1910.

Midland Beach.



No sewers discharge directly into the lower bay at Midland Beach.

The privy system is almost universal with a few cesspools.

A few small sewers and cesspool overflow pipes discharge into trenches dug in the marshes back of the resort.

These trenches drain the mosquito-breeding swamps and eventually discharge their contents into the creek separating South Beach from Midland Beach, so that the sewage constituents may reach the bay through this creek.

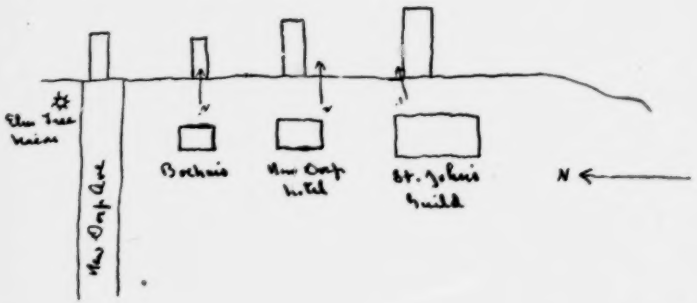
1 main sewer discharges into trenches the sewage from 3 hotels and several cottages.

9 June 22, 1910.

New Dorp Beach.

There are three (3) sewers discharging into the bay along this beach.

A 6″ sewer pipe discharges just beyond low water mark in front of Boehm's Picnic Grounds. The outlet is under the pier.



The greatest source of pollution along this beach is from the Seaside Hospital of St. John's Guild.

Just in front of the hospital beside the long pier is a 1½′ sewer outlet under a pile of rocks 20′ beyond low water mark.

The water contains many sewage particles especially toilet paper.

On the northern end of the bathing beach in front of the hospital there is another sewer outlet under a pile of rocks about 20′ beyond low water mark.

The other hotels and private houses have privies or cesspools. None of them directly pollute the bay.

10 June 23, 1910.

Great Kills.

The chief sources of pollution of the Great Kills are three sewers and one overhanging privy.

A small sewer discharges under a pile of rocks about 30′ beyond low water mark just south of Greenwadd's Hotel.

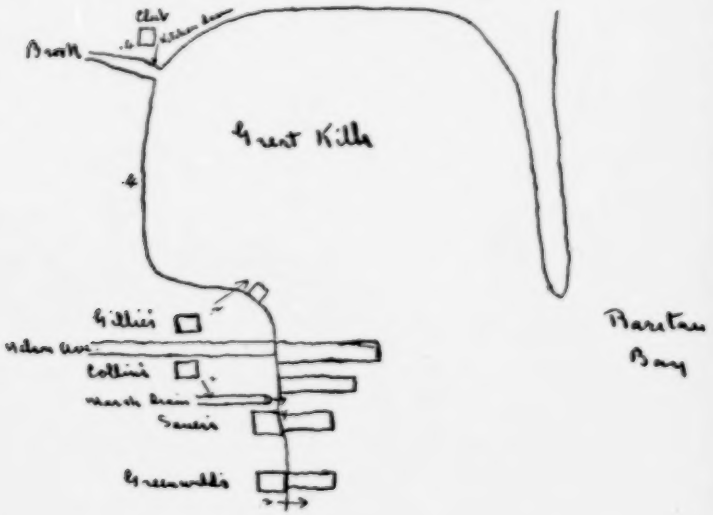
An overhanging privy in Sauer's Hotel pollutes the water the discharge being on land only at low water.

Just north of Sauer's Hotel a 2′ pipe discharges just above high water mark. It drains the swamps back of the hotels and received the sewage from Collin's Hotel, the sewer pipe entering the drain near the hotel. (So informed, pipe not seen.)

Just north of Gillie's Hotel a small sewer from the hotel discharges into the Kills.

The private houses to the north of the hotel section are mostly back from the shore and are provided with privies or cesspools which do not pollute the Kills, at least directly. One (1) privy near the shore may pollute the water in case of an overflow.

The brook entering the Kills at the Yacht Club drains an ice pond.



A drain enters it which discharges dishwater from the Yacht Club kitchen. No other sewage so far as could be learned is discharged into this brook. This brook was made the subject of a sensational article on shellfish pollution in the N. Y. Journal a few years ago.

11 June 23, 1910.

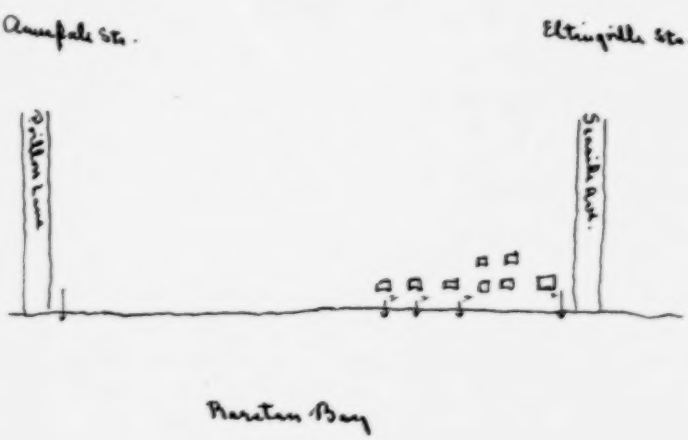
Great Kills.

The Yacht Club and private houses near this brook are provided with privies, which do not pollute the Kills directly. The Yacht Club privy would in case it overflowed, or in case of a very heavy rain.

The worst spot along the Kills is just north of Sauer's Hotel near the foot of Nelson Avenue, already described.

12 Jne 27, 1910.

Eltingville Shore.



Just south of Great Kills near the foot of Seaside Avenue, Eltingville, there are about twenty (20) cottages and a fishing club near the shore.

Four (4) small sewers discharge the sewage from these houses, the outlets being under piles of rocks just beyond low water mark in three cases, and above high water mark in one cases.

The amount of discharge is very small.

Annadale Shore.

One small private sewer discharges into the bay near the foot of Poillon Lane.

13 June 24, 1910.

Latourette Pond.

The Schwab Foundling Hospital discharges the sewage from 200 inmates into a septic tank. After treatment, the efficiency of which is very doubtful, from mere inspection, it is discharged into the bay at the south side of the pier near low water mark.

The overflow brook from Latourette Pond empties into the bay near this same pier. There is another overflow north of the hospital grounds. It contains no sewage.

Two hundred feet south there is an overflow into the bay from a cesspool at Brunner's Hotel. At Winter's Hotel there is a privy 50 feet back from the shore.

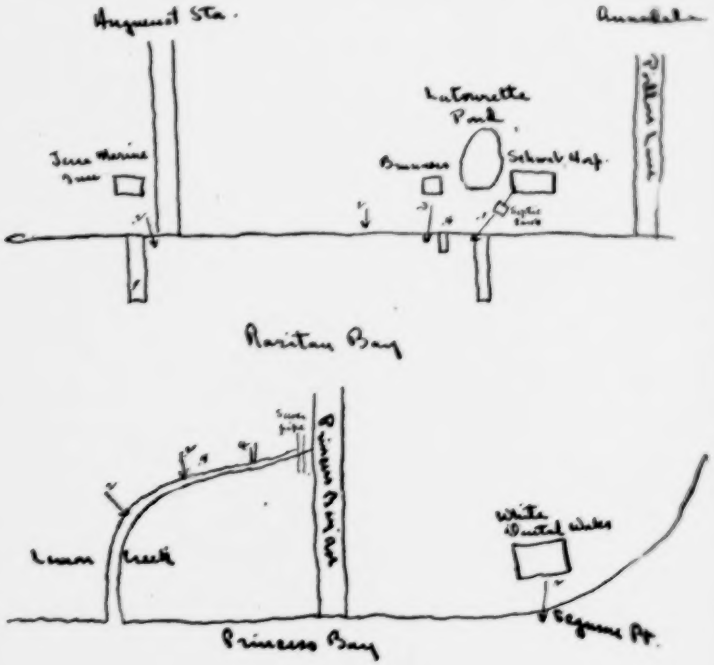
Hug-enot Shore.

A large hotel, 200 capacity, the Terra Marine Inn, discharges its sewage direct into the Bay by a 6″ pipe. About 500 feet north of this, a wooden drain discharges sewage from a group of private houses.

Sequine Point.

The White Dental Works, 600 hands, discharges sewage from a one foot pipe at high water mark in front of the factory. Two private sewers, a one foot pipe and a 3″ x 1′ wooden drain, empty into Lemon Creek, near its outlet into Princess Bay.

There are two privies near the bank of creek and a one foot sewer pipe crosses the bed of the creek, heading toward Princess Bay. No outlet could be found, but pipe leaks into the creek from cracks.



Red Bank.

The Loretto Mission, 200 inmates, discharges its sewage into the Bay at this point.

Tottenville.

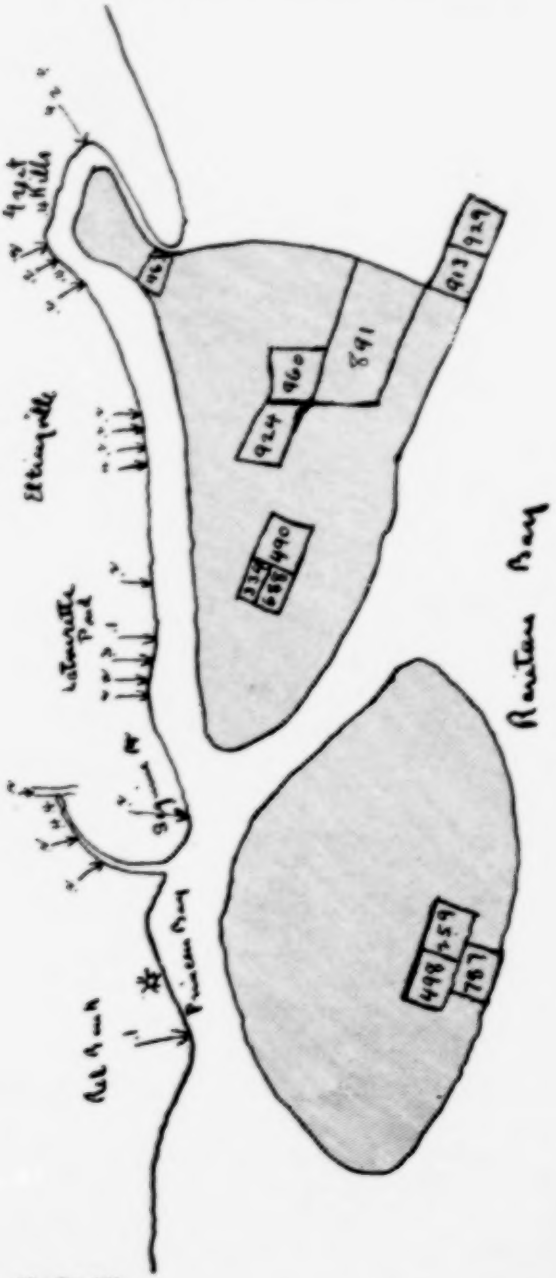
Here there is a public sewer system with four outlets into
14 Arthur Kill. Two 6" pipes discharge sewage into the Kill near Perth Amboy ferry, near the large main sewer pipe.

On the Raritan Bay side of Tottenville, ten small private sewers discharge into the Bay; their combined discharge is not great.

Raritan Bay

June 25th, 1910.

Results of Inspections were plotted on U. S. C. & G. S. Chart #120.



15 Conclusions.

Leaving out of account the Tottenville sewers discharging into Arthur Kill, which are so remote as to be comparatively unimportant, the pollution of the water of Raritan and New York lower bay- by sewers on the south shore of Staten Island is very slight. The heaviest points of discharge are at Red Bank, where the Loretto Mission is located, at Segamine Point from the White Dental Works and at New Dorp from St. Johns Guild.

Oyster beds located quite near the shore would undoubtedly feel the effect of the local sewers and this is especially true in Great Kills where some beds of other concerns are situated quite near the sewer outlets.

This shore of Staten Island is a place of summer residence almost entirely and during the chief part of the oyster season there would be very little sewage pollution with the exception of Loretto Mission and the White Dental Works.

1 COMPLAINANTS' EXHIBIT No. 196. James D. Maher, Commissioner.

Lederle Laboratories,
39-41 West 38th Street, New York City.

Report in the Matter of Testing of Oysters for the Effect of Temperature upon the Activity of the Adductor Muscle Which Controls the Opening and Closing of the Oyster Shell.

2 Lederle Laboratories,
Sanitary, Chemical, and Bacteriological Investigations,
39-41 West 38th Street, New York City.

Joseph A. Deghuée, Ph. D.
Frederic D. Bell.
Harry E. Bramley.
Herbert D. Pease, M. D.

September 16th, 1912.

Report.

The sample of oysters was brought to me by Mr. George W. Sanbeg on September 14, 1912, from Bed #490, off Great Kills, Staten Island. These oysters were placed in a refrigerator held at a temperature of approximately 38° F. for over night. At the same time, several gallons of sea water which were collected off the Battery, showing a specific gravity test of 10/19 were likewise placed in the refrigerator until the next morning.

On the morning of September 15, seven (7) of the oysters and two (2) quarts of sea water were placed in separate vessels in another refrigerator and were cooled to 36° F. To the two (2) quarts of the sea water there was added 1/10 of a gram of Merck's Medicinal Fuchsin and thoroughly dissolved. This fuchsin solution was then added to the 7 oysters and the vessel containing the same was allowed to stand at a temperature of from 34 to 36° F. until 6:30 P. M. The entire group of 7 oysters was then washed in brine at a temperature of 35° C. for the purpose of washing off all traces of the fuchsin solution. Three of the oysters were then opened and the shell liquor collected in a flint glass bottle. Inspection of the opened oysters failed to show the slightest traces of fuchsin coloration on the inside of the shell, on the tissues of the oyster, or in the shell liquor. The shell liquor was preserved until the morning of the 16th, for the purpose of determining by daylight whether
3 the liquor *contains* the slightest tinge of fuchsin coloration. It was found that it was entirely without such coloration.

A fresh solution of fuchsin in 2 quarts of sea water of the same concentration was made, and the remaining 4 oysters of the 7 orig-

inally taken, were placed in this solution and left at room temperature. They were allowed to remain in this solution for a period of 22 hours at an average temperature of 65° F. At the end of that time, the oysters were opened and the following results noted: The gills of the oyster were turned a dark fuchsin color, the mantle were slightly discolored on the inner surfaces, the body of the oyster was not colored with the fuchsin to any extent. On opening the oysters, the shell liquor was found to be comparatively free from color. The inner surfaces of the shell were also uncolored.

Interpretation.

The results of this investigation would demonstrate that oysters kept in water at a temperature of 34 to 36° F. will remain closed, and that even water soluble dyes in solution of sea water fail to gain entrance to the cavities of the oyster inside of the shell. As the particles of these dyes in aqueous solution are infinitely smaller than the bodies of bacteria, it would be a warranted conclusion that the complete closure of the shell, such as occurs at this temperature, would be the means of total exclusion of the bacteria in the water surrounding the shell gaining entrance to the oyster inside of the shell.

7 *Disposal of Sewage.*

This has been a most difficult problem and has been considered by committees of our boards, by civic bodies and by committees of citizens. We have had the opinion of the best experts on the subject. One point is conceded and that is no matter what system of sewage disposal is adopted Paterson must change from a combined to a separate system of sewers. For a year, at my direction, the City Engineer has been studying this question and worked out a plan by which we will be enabled to change our system for a great deal less than was first thought possible. The sewers built for the last two years have kept this plan in view.

The plan of the City Engineer for a separate system, which accompanies this message, should be adopted and put into operation. This can be done gradually and without being too great a burden.

Heretofore, the Lakeview section of the City has been neglected. At my direction, the City Engineer has prepared a plan for sewering this section, the development of which has been hindered by the lack of this necessary provision. A system could be extended through this section at a reasonable cost. The main trunk could be built for about $25,000, part of which could be assessed upon adjoining property, leaving probably from ten to fifteen thousand dollars to be raised by sale of bonds.

The Stony Road section is hindered by a like lack of sewage facilities, and the Engineer should be instructed to work out a plan for the sewage of that section.

The main question of disposal of the sewage has not been decided. If a trunk sewer can be built for the money reported by the Sewage Commission, and permission can be had to empty the same into New York Bay without purification works, then Paterson should join in the plan. If the sewage must be purified, as we have every reason to believe, then there is no reason for extending the sewer to New York Bay. The great expense of a tunnel to New York Bay should be avoided and the purification works built on Newark meadows.

Paterson will maintain the position that no matter what plan is adopted this City will not enter into any final contract with the Commission until the exact cost is ascertained by bids from reputable contracting firms.

8 Engineering works of this kind are generally estimated to cost considerably less than the final actual cost. We should be sure that the trunk sewer plan will cost us no more than a separate disposal works.

If the present financial management of the City is continued the City will be able to assume the burden of this problem without great detriment.

The likelihood of this burden being cast upon us has ever been uppermost in the minds of the Finance Commission and myself and makes it necessary that even stricter economy be practiced in the future in order to prepare for the shock which the assumption of the debt and expense of sewage disposal will cause the City.

Executive Secretary.

Preliminary Reports on the Disposal of New York Sewage.

IV.

Study of the Collection and Disposal of the Sewage of the Upper East River and Harlem Division.*

Metropolitan Sewerage Commission of New York.

George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sooysmith, Linsly R. Williams, Commissioners.

July, 1912.

1 *Study of the Collection and Disposal of the Sewage of the Upper East River and Harlem Division.*

Honorable William J. Gaynor, Mayor of the City of New York.

SIR: In Preliminary Report No. 1, dated September, 1911, the Metropolitan Sewerage Commission divided the territory covered by the City of New York into four parts to facilitate the design of main drainage works for the protection of the harbor against excessive sewage pollution. The works for the Jamaica Bay Division, one of these parts, were described in a report dated December, 1911. The present report deals with a general plan for main drainage and sewage disposal for a second part, known as the Upper East River and Harlem Division, which embraces the land in the Boroughs of the Bronx and Manhattan, which drains to the Harlem river, and the land in the Boroughs of the Bronx and Northern Queens which drains to the Upper East river.

The plan here set forth is the result of careful study based on the outlook in the year 1912 for the municipal development of the region under consideration and on the existing state of the art of sewage disposal.

All the work planned will not be required in the immediate future, but it is regarded as necessary that such main drainage work as is undertaken by the city should conform to these plans, or such modifications of them as may be determined upon. The possibility

*This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service. Some features of this report will remain open for revision until the final report is submitted.

that a more complete system of main drainage than is here proposed may be needed in the distant future has been kept in mind in preparing these plans and it is believed that the works can be economically adapted to afford a more thorough protection of the harbor in the case of necessity.

The most prominent feature of the plan is the discharge of the sewage, after partial purification, into the large, deep tidal channels as near the sound entrance of the harbor as practicable.

The works are intended to deal with the dry-weather flow of sewage as collected in the lateral sewerage systems now built on the combined system. Where no sewers have yet been constructed, it will generally be desirable to build them on the separate system; this will not only facilitate a removal of the impurities, but contribute to economy of construction.

Topographical Features of the Division.

The Harlem river and the Upper East river determine the principal topographical features of this division. The Harlem
2 river runs through a narrow valley with shores which are in part densely populated, or are certain to become so at no distant day. The shores of the Harlem are nearly parallel, the stream resembling, in some respects, and being actually in part, a canal. The water is already so overburdened with sewage that no system of diffusion or other partial remedy is capable of sufficiently improving it. There is not room on the drainage area of the Harlem for purification works capable of sufficiently improving the sewage to permit of its discharge into these waters, and consequently the sewage must be taken elsewhere.

The shore lines on both sides of the Upper East river are markedly irregular; the water surface being characterized by a series of large, shallow bays along the whole length, separated by long, narrow points of land.

The water in the main channel which flows through the Upper East river is not now overburdened with sewage, nor is it likely soon to become so. It has a large capacity for assimilating sewage provided the sewage is properly treated and then discharged directly at the bottom of the tidal stream.

The parts of this territory which present difficulties to main drainage are chiefly flat, low-lying valleys which extend long distances inland from the shallow bays of the river.

Except in the closely built-up part of this division, which is, or will be, tributary to the Harlem river, the population in the territory included in this report is chiefly of a semi-rural residential character, located in numerous growing villages not largely devoted to manufacturing. The future of this division seems to lie in its more complete occupation for residential purposes. The configuration of the shore, the shallowness of the water, except in the main channels, and the distance from the metropolitan centers of commercial activity are opposed to the extensive development of this section for the uses of manufacturing and transportation.

Bathing beaches, camps and other provisions for recreation at moderate expense during the summer months are now more or less numerous and seem destined to increase in popularity unless the pollution of the harbor water should become so great as to be too objectionable.

Formerly shellfish of excellent quality were gathered in large numbers in the Upper East river, and even at the present time hard-shelled clams are dredged near where the river joins Long Island Sound. Except for small boats, yachting, which was, and is, enjoyed by many persons in the Upper East river, has, for the most part sought Long Island Sound for the clearer water, lesser tidal currents and greater freedom from traffic which there prevail.

3 Separation of the Division Into Five Parts for Main Drainage Purposes.

To facilitate the sewerage and drainage of the Upper East river and Harlem division the entire territory has been separated in this report into five sub-divisions.

In each sub-division the sewage is to be collected to a central point for treatment and discharge. The boundaries of the five sub-divisions follow:

1. The Harlem Sub-division comprises the land in the Borough of Manhattan, north of 82d Street, naturally draining to the Harlem river, and that part of the Borough of the Bronx lying west of the Bronx river, except a narrow strip draining to the Hudson river.

2. The Eastern Bronx Sub-division comprises that part of the Borough of the Bronx which lies east of the Bronx river. Westchester, Unionport and Van Nest are situated within this area.

3. The Northwestern Queens Sub-division comprises the northwestern part of the Borough of Queens, draining mostly to Bowery bay and to the westerly shore of Flushing bay, and includes North Beach, Woodside, Steinway and a part of Corona.

4. The Corona-Flushing Sub-division comprises that portion of the Borough of Queens, tributary to the East river, which extends from the southeastern boundary of sub-division 3 southerly to the main divide of Long Island and easterly to a line running through Whitestone and Ingleside. Most of this area lies in the Flushing creek drainage basin. Winfield, Elmhurst, Corona, Flushing and College Point and parts of Whitestone are situated within its limits.

5. The Northwestern Queens Sub-division comprises that part of the Borough of Queens, tributary to the East river and Little Neck bay, which lies east of the limits of sub-division 4. Douglaston, Bayside and parts of Whitestone are included in this area.

Points for Concentration and Discharge of the Sewage.

The sewage will be collected to as many points as there are sub-divisions.

The sewage of the Harlem Sub-division is to be carried to Ward's Island, where it is to be treated and the effluent discharged into the swift currents of Hell Gate.

4 The sewage of the Eastern Bronx Sub-division will be collected near Clason Point, where, after treatment, it will be discharged into the deep water of the Upper East river.

The sewage of the Northwestern Queens Sub-division will be carried to a point in the neighborhood of Hell Gate and there discharged.

The sewage of the Corona Flushing Sub-division will be brought to Tallman Island, where treatment works can be located. The sewage will be discharged into the East river under conditions favorable for diffusion.

The sewage of the Northeastern Queens Sub-division will be carried to Cryder's Point, just west of Little bay and opposite Throgs Neck. There the sewage can be discharged into deep water at the extreme east end of the East river.

Methods of Treatment.

NOTE.—The methods which are proposed in this report for treating the sewage are such as have been thoroughly tested and found by the experience of many cities to give good results, while not designed to afford a high degree of purification, the processes are among the most reliable, least offensive and most economically known, and are believed to be capable of removing the impurities of the sewage to such an extent as to permit of the effluent being discharged into the harbor under suitable conditions without offense.

Eventually the growth of population and the consequent increase in the quantity of sewage produced probably will require that more complete methods of treatment shall be employed, or that the sewage shall be taken to some other place for disposal. It is impossible to foretell with accuracy when that time will arrive, but the Commission is of opinion that the works now planned will afford all the protection which the harbor will require for the next forty years, or until about 1952. As to the methods of treatment which ultimately will be needed, it is equally difficult to prophesy; the art of sewage purification has by no means reached perfection, and if the progress of the next forty years equals the accomplishments of the last twenty, a not unreasonable anticipation, marked improvements may be expected in the efficiency, economy and reliability of existing methods, if not the introduction of new processes, which will be revolutionary in character.

The probability that it ultimately will be necessary to protect the harbor against sewage to a greater extent than the requirements of the present or discoverable future require has been clearly recognized by this Commission from the first and has been kept in mind in making the plans here proposed with the object that these works might form part of a more comprehensive scheme of dealing with the sewage when that becomes necessary.

Methods of Treatment Proposed.—After a careful study of the question of the form of treatment required for the sewage of the Upper East river and Harlem Division, due regard being had to the needs of each of the five outlets, the conclusion has been reached

that fine screening or coarse screening and sedimentation will, for some years, give an effluent of satisfactory character for discharge into the water of the East river.

Where sedimentation tanks are to be used, coarse screens will be employed to protect the pumping machinery and to keep large floating matters from causing trouble in the tanks and from passing out through the outfall.

5 In all cases grit chambers will be placed on the lines of the main trunk sewers at or near the treatment works. In these chambers the sewage will be given a settling period of from one to two minutes, the velocity being reduced sufficiently to allow the heavy mineral detritus borne by the sewage to be deposited, but not enough to permit much organic matter to settle.

The grit chambers will afford protection to the pumps and will keep the proposed long and deep outfall pipes clear of gritty deposits wherever sedimentation tanks are not used. Where sedimentation tanks are planned, the grit chambers will first rid the sewage of suspended matter of a kind which would cause trouble and be difficult to handle if allowed to settle in the tanks. Grit chambers are specially useful where combined sewers are intercepted or form a part of the collecting system, as will largely be the case with the main drainage systems as here proposed for New York City.

The treatment works at Ward's Island, Clason Point and Tallman Island, for the Harlem, Eastern Bronx and Corona-Flushing Subdivisions, respectively, should consist of grit chambers, coarse screens and settling tanks. Fine screens and grit chambers at the foot of Winthrop Avenue, Long Island City, will suffice for the treatment of the sewage for the Northwestern Queens Sub-division; the sewage from the Northeastern Queens Sub-division should be passed through grit chambers and fine screens at Cryder's Point, Beechurst.

If it were deemed necessary to purify the sewage from the Harlem Sub-division to a greater extent than would be done by sedimentation or chemical precipitation, it is doubtful if its further purification could undertaken either at Ward's Island or at any other place in the vicinity. The area of land required for percolating filters, to treat the large volume of sewage which is to be brought to Ward's Island, would require more land than is available, and the odors which might be produced by their use would be objectionable in this location.

The amount of sewage to be discharged from Queens into the East river at Winthrop Avenue, although large in the distant future, will, for many years, be considerably less than the quantity brought to Tallman Island. It will never be more than a small proportion of the amount to be discharged into the river from the Ward's Island sedimentation plant, only a few hundred feet distant from Winthrop Avenue. In view of this fact, screening is the only form of treatment deemed necessary for the sewage of the Northwestern Queens Sub-division. If a more thorough treatment be needed in the future, when the volume of sewage becomes greater, it will be possible to carry the sewage by means of a tunnel under the East river to the disposal works at Ward's Island; or the necessary land

for a pumping station and settling tanks may be procured in the Borough of Queens.

6 The amount of sewage to be discharged at Cryder's Point probably will always be comparatively small and the opportunity for its diffusion and digestion in the waters of the East river is favorable; therefore screening is the only treatment required for the sewage of the Northeastern Queens Sub-division.

Sites for Treatment of Works.

Harlem Sub-division.—After considering many projects for the collection and disposal of the sewage of this sub-division it becomes evident that it would be uneconomical to take the sewage further from Hell Gate, provided a suitable site for treatment works could be found in that vicinity.

For a time it seemed likely that Riker's Island might offer every necessary facility for the disposal of the sewage, not only of the Harlem, but of most of the other sub-divisions. The area of Riker's Island is large enough for any works which might be needed, the situation is remote from inhabitated shores and the island, as yet but little occupied, already belongs to the City.

Upon investigation, Riker's Island was found to be unsuitable as a site for sewage disposal works. Composed of uncompacted refuse from New York City, the stability of the island is too uncertain to warrant the construction of the extensive engineering works required, and large sums of money would have to be spent for grading in order to save the excessive cost of pumping the large volume of sewage to the present level of the island.

The island known as Sunken Meadow was examined, but was found to require too much improvement to warrant its use as a location for sewage disposal works.

A better and a satisfactory location for the works required lies at the northeast corner of Ward's Island. This island is more favorably located than Riker's Island in respect to the economical collection of the sewage, and the land at the proposed site is low, firm and of sufficient extent for such works as will be required. The island belongs to the City of New York and is partly occupied by public institutions. No injury would be done by employing the corner selected for treatment works. Deep water lies close to the island; the shore is smooth and the currents are swift. The opportunities for an immediate diffusion of the sewage in the water are perhaps better at this place than at any other point in the whole metropolitan district, owing to the mixing action of the currents.

Eastern Bronx Sub-division.—Two large areas of marsh land, southwest and southeast of Unionport, were at first considered as sites for sewage disposal works, each being of ample size, but both situated far from deep water. A more favorable site for the location of

7 such disposal works as will be needed for this sub-division exists near Clason Point, where the ground is low and firm, and the deep and swift currents of the main channel of the Upper East river pass near the shore. A large part of the sewage from this sub-division will be brought to Clason Point by the drainage system now

under construction, and the remainder can be collected at low cost.

Northwestern Queens Sub-division.—Most of the land in the Northwestern Queens Sub-division drains naturally to Flushing and Bowery bays, but owing to the shallow water and absence of currents capable of mixing with the sewage and carrying it away, there is no point in either bay where large quantities of treated sewage should be discharged. The nearest suitable point for the discharge of the sewage, after the removal of the suspended matter, is Hell Gate, near the foot of Winthrop Avenue, and directly opposite the proposed Ward's Island treatment works. The volume of sewage to reach this place probably will be small for many years, and such land as is needed for the simple treatment required can be procured without great difficulty or expense.

Corona-Flushing Sub-division.—A large proportion of the sewage of the Corona-Flushing Sub-division can easily be concentrated near the mouth of Flushing creek and the rest can be collected by a sewer running from that point to Tallman Island, where treatment works should be located.

Tallman Island is the nearest point to the mouth of Flushing creek at which treatment works, of a kind requiring the discharge of the effluent into deep water and swift currents, can satisfactorily be placed. Both land and water conditions are suitable at this point for the location of disposal works and the discharge of the effluent. The site is practically devoid of improvement and little or no injury will be caused to future development by such works as are proposed. Deep water exists at a short distance from shore, and the volume and character of water flowing past this point are favorable for the digestion of a large quantity of sewage.

The comparative ease with which the sewage from that part of the Flushing Creek Sub-division which lies west of the creek, can be united with that from the neighborhood of Flushing and brought to Tallman Island, makes it desirable that such disposition of the sewage should be made. The sewage should not be carried to Hell Gate, for this would be more expensive and increase the burden which the water of the East river has to bear near the densely populated districts of the city.

8 Northeastern Queens Sub-division.—The only practicable place for the discharge of the sewage of the Northeastern Queens Sub-division, unless intensive treatment be employed, is the East river, between Whitestone Point and Cryder's Point. The latter is the more suitable place both for the collection and the discharge of the sewage. The East river offers better opportunities for the reception of sewage off Cryder's Point than it offers at Tallman Island or Clason Point. As the amount of sewage will probably be comparatively small, for at least a great many years, and the conditions for the digestion of the discharged sewage by the water are favorable, fine screening is the only treatment deemed necessary at this point. There should be no objection to the presence of a screening plant, provided the appearance of the building conforms with the surrounding development.

Instead of carrying the sewage of Bayside and Douglaston to Cryder's Point, as is here proposed, it is possible to treat it on per-

colating filters which can be built on the marshes near Alley creek, but as these might be objectionable to the residents of the neighborhood, the plan is not considered advisable.

Outlets.

Location and Depth.—The sewage will be discharged in every case at a distance from the shore, the position of the outfall depending upon the nearest point at which water of suitable depth can be found. It is proposed always to have the sewage discharged at depths of from 30 to 50 feet, and in such manner as to give a favorable opportunity for its admixture with the water of the river. In order to facilitate diffusion, it will be desirable to discharge the sewage from each point at more than one outlet.

Systems of Main Drainage.

Character of Sewers Proposed.—The main collecting and intercepting sewers, as planned by the commission for the Harlem, Eastern Bronx and Northwestern Queens Sub-division, will carry only the dry-weather flow of the contributing combined sewers, already built or to be built, in these districts. They are not designed to carry any portion of the storm flow. Overflows from these main dry weather sewers will allow the storm water to pass directly to the water courses. The commission does not believe that, in this district at least, the advantage gained by the treatment of the storm water, at the works proposed would warrant the extra expense involved in that procedure.

9 The main collecting and intercepting sewers, planned by the commission for the Corona-Flushing and Northeastern Queens Sub-divisions, will carry only house sewage. In these areas it is especially desirable that all new sewers be built on the separate system. Throughout this territory, few sewers of any kind have as yet been built. Practically the only combined sewers are in the villages of Flushing, Ingleside, College Point and Whitestone. The commission's plans and estimates for main drainage systems in those two sub-divisions have been made so as to utilize the existing sewers as far as practicable, and on the assumption that the dry weather flow from the existing combined sewers would be intercepted but that all sewers hereafter built tributary to these systems would carry only house sewage.

Relative Merits of Separate and Combined Sewers.—Although this commission is aware that the Board of Estimate and Apportionment of the City has approved preliminary drainage plans prepared by the Sewer Bureau of Queens Borough for a large portion of the Corona-Flushing Sub-division, and that these plans call for combined sewers, except in the low lands where the street grades to be established make combined sewers impracticable, discharging into Bowery bay all the sewage originating west of Flushing creek, the commission believes it to be desirable to provide more protection than these plans afford for keeping the waters free from sewage.

In the judgment of the commission, the character of the territory and of the neighboring waters make separate, instead of combined, sewers generally advisable for the Corona-Flushing and Northeastern

Queens Sub-divisions. Although the growth of population in many parts of this large area has been rapid, and with the extension and betterment of transit facilities is likely to be still more rapid in future, the total population at present is relatively small, and most of it is gathered into a number of more or less isolated residental communities. Large areas of unoccupied land exist. Notwithstanding the probable increase in poulation, the several communities may be expected to preserve their separate identities for many years. In these villages there probably will be only comparatively few parts which, in the near future, will support a dense population. Only small portions of the territory will need complete systems of drains for the removal of storm water. If the house sewage is removed by means of separate sewers, these can be of small size in comparison with those that would be necessary in case storm water were also to be provided for in the same system, whereas the surface water may, in many cases, be discharged into near-by water courses, such as Flushing creek, without harmful consequences. Separate sewers can thus be made to save for the present the cost of constructing the large and long storm water drains that will be necessary when the land around these creeks is fully developed. The construction of some of these long main drains can be undertaken gradually, as the need for them becomes evident through the development of the territory.

Practically all the unsewered communities in the Corona-Flushing Sub-division are in need of sewers for the removal of household wastes. But if the house sewage from these comparatively small and isolated centers of population were to be collected and carried away in combined sewers enough to take care of the storm water drainage of the districts when they shall have become densely built up in the future, not only will the present per capita cost of construction be unnecessarily high, but also the small dry weather flow in the large sewers will cause deposits to form on their bottoms, give rise to septic conditions and make a high cost for maintenance.

It would be inadvisable to recommend the installation of separate sewers in the Harlem Sub-division, as the population is practically all served at present by combined sewers, and future extensions of the same character have been planned to such an extent as to make a recommendation to this effect unwise.

In the Eastern Bronx Sub-division, also, the installation of separate sewers would not be warranted, as much of the drainage system is already under construction, and comparatively little additional work is necessary in order to bring all the sewage of the district to Clason Point.

Although the separate system would be well adapted to such a development of the land as may be expected in the Northwestern Queens Sub-division for many years, and would also serve better to protect Bowery bay from pollution during periods of storm, certain considerations make the separate system inadvisable in this territory. The treatment which is projected for the sewage in the near future is passage through grit chambers and screens. At some future time many parts of this territory are likely to be occupied by a rather dense population. Moreover, preliminary plans, contemplating the installation of combined sewers, have already been made by the

Bureau of Sewers of the Borough of Queens and approved by the Board of Estimate and Apportionment.

Collecting Sewers for the Harlem Sub-division.—The sewage of the Harlem Sub-division will be collected at Ward's Island by means of intercepting sewers which will follows both banks of the Harlem river and the north shore of the Upper East river west of the Bronx river, and connect with Ward's Island by means of tunnels.

The sewage of that portion of Manhattan which drains to the Harlem river between 82d Street and 162d Street will be collected
11 at a point in Thomas Jefferson Park just south of the corner of Pleasant Avenue and 114th Street. The south intercepting sewer will run from 86th Street and East End Avenue northerly to its junction with the north intercepting sewer in Thomas Jefferson Park. In this park, near the water-front, the sewage from both of the interceptors will be passed through grit chambers and coarse screens, and will then be carried to Ward's Island by means of a deep tunnel bored through solid rock.

The sewage of all that portion of the Bronx which drains to the Harlem river and the Bronx Kills will be collected by an intercepting sewer starting at 192d Street and following as closely as practicable the easterly shore of the Harlem river at the corner of 132d street and Willow Avenue. The dry weather flow from Marble Hill and the territory around Spuyten Duyvil will be brought by gravity into the existing Broadway sewer, while that from the low land west of Kingsbridge will have to be pumped into the sewer, which is to be intercepted at 192d Street.

The intercepting sewer along the Bronx shore of the Harlem river will receive also the dry weather flow from those areas in Manhattan north of 162d Street which drain to the Harlem river, with the exception of the sewage from a small district at the extreme northern end of the island which can be better served by having its dry weather flow pumped into a sewer at the corner of Seaman Avenue and Hawthorne Street, from which it would find its final outlet in the Hudson river at the foot of Dyckman Street. The sewage which is to be carried from Manhattan to the Bronx interceptor will be collected at 172nd Street and 201st Street by short intercepting sewers, passed through grit chambers and coarse screens and siphons under the Harlem river.

That portion of the Bronx west of the Bronx river which drains to the Upper East river will have its dry weather sewage flow collected by an intercepting sewer running from the vicinity of the Farragut Street sewer outlet at Hunt's Point to the corner of 132d Street and Willow Avenue.

At 132d Street and Willow Avenue, the sewage from the two Bronx intercepting sewers will be passed through grit chambers and coarse screens and then carried to Ward's Island by means of two deep tunnels of the same character as the one bringing the sewage from Manhattan to that place. It will be necessary to build only one of these tunnels in the near future.

As most of the area included in the Harlem Sub-division is either closely built up or is rapidly increasing in population, the collecting sewers have been designed by the commission to take care of the dry-weather flow that may ultimately be expected. The topography

and other conditions are such as to make adequate relief sewers expensive and difficult to construct.

12 Allowance in the estimates has been made for placing automatic regulators at the points in connection with the combined sewers, so as to control the flow into the interceptor from each sewer during period of storm. Allowance has also been made for the cost of such lateral sewers as will be necessary to bring to the main intercepting sewers the dry-weather flow from the outlets of the combined sewers. Most of the combined sewers are at such elevations that tide-gates will be required so as to prevent harbor water from entering the intercepting sewers; and tide-gates have been taken into account in estimating the cost of the project.

A pumping station will be located on Ward's Island, for the purpose of pumping all the sewage of the Harlem sub-division into the treatment tanks to be installed there. Final discharge of the clarified sewage will be through tunnels outletting into the East river opposite Ward's Island.

Collecting Sewers for the Eastern Bronx Sub-division.—The sewage from a large portion of the Eastern Bronx sub-division will be collected at Clason Point by a system of combined sewers now under construction. These combined sewers will be provided with storm-water overflows at various points along the Bronx river and Westchester creek.

In accordance with plans outlined by the Bronx Bureau of Sewers, another portion of this sub-division, lying east of Westchester creek, will be drained by a trunk sewer outletting at old Ferry Point; and the sewage of the remainder of the district, which drains to Eastchester bay, will be carried to an outlet on the south side of Throgs Neck.

A short intercepting sewer and a pumping station station will be all that is required to transfer the dry-weather flow from the Old Ferry Point sewer to the sewer which is to discharge at Clason Point. At a later period, another intercepting sewer could be constructed along the water-front from the pumping station to a point near Throgs Neck, in order to intercept the dry-weather flow from the district draining to Eastchester bay. The cost of this sewer has not been included in the estimates, as it will not be necessary to build it in the near future at least.

The sewage thus collected at Clason Point, after passing through grit chambers and coarse screens, will be pumped to treatment works located at that place, and the effluent discharged through submerged outlets into the East river.

The sewage of the district draining to Eastchester bay will be discharged untreated into deep water in the East river close to the junction of the East river with Long Island Sound. If at some future time it is thought advisiable to discontinue the discharge of raw sewage at this point, a connection can be made with the pumping station a Westchester creek, as previously mentioned; or treatment works can be installed in the vicinity of the outlet.

13 Collecting Sewers for the Northwestern Queens Sub-division.—The dry-weather flow from the Northwestern Queens Sub-division will be brought to the East river at the foot of Winthrop Avenue, Long Island City, by means of an intercepting sewer start-

ing on Ditmars Avenue north of Astoria Avenue, Corona, and running along the shores of Flushing bay and Bowery bay, passing thence through Steinway to its final outlet. The sewage will be passed through grit chambers and fine screens before being discharged.

With the street grades as now established, all the sewage of this area, with the exception of that from several small districts along the water-front, can be discharged into the East river by gravity. When these districts are developed, several small automatic pumping stations can be installed to pump the sewage into the main intercepting sewer. In order that the dry-weather flow from two large interior districts may be brought by gravity into the main interceptor, long dry-weather cut-off sewers will have to be constructed to intercept, at a considerable distance from the water front, the combined trunk sewers which are proposed for the drainage of these districts. The topography is such that these cut-off sewers can intercept the dry-weather flow from the combined lateral sewers which will connect with the main trunk sewers below the points from which the cut-off sewers start.

Preliminary drainage plans covering this territory have been prepared by the Queens Borough Bureau of Sewers and approved by the Board of Estimate and Apportionment. The plan proposed by the Commission interferes but little with any of the combined sewers proposed by the Bureau, except the main sewer along the water front, and affords a more favorable point for the discharge of the dry-weather flow. The storm water will be discharged directly into Flushing and Bowery bays. The main intercepting sewers along the shores of these two bays, as prososed by the Bureau of Sewers, becomes unnecessary. Steps have been taken by the Bureau of Sewers to build this sewer for the present only to a point on the southwesterly shore of Flushing bay, south of the outlet from Jackson Mill Pond. This sewer will continue to dispose of the storm water from the areas draining to the southwesterly shore of Flushing bay, while the dry-weather flow from the laterals discharging into it would be intercepted by the sewer proposed by this commission.

No satisfactory method of relieving the intercepting sewer for the Northwestern Queens Sub-division, at a reasonable cost, is apparent, and therefore this sewer has been designed by this commission to have sufficient capacity to provide for a dry-weather flow which is not likely to be exceeded for a great many years.

14 Collecting Sewers for the Corona-Flushing Sub-division.—The house sewage from practically the whole Corona-Flushing Sub-division will be brought to Tallman Island by a main trunk sewer which will start in Winfield and run through Elmhurst and across the marshes, south and east of Corona, to Flushing creek. The sewer will pass under the street by means of a siphon and will follow the easterly bank of the creek through Flushing. From this point the sewer will cross the marsh to College Point and continue to Tallman Island.

The sewage from the tributary areas will be brought to the main sewer by many trunk and lateral sewers. One of the more important of these branch sewers will start near Forest Park and join the main trunk sewer on the meadows not far from Strong's Causeway.

Another, joining the main sewer just after it crosses Flushing creek, will drain the Mill creek valley and provide a much needed outlet for the dry-weather flow from the existing Ingleside trunk sewer. Still another sewer, with several main branches, will drain that part of Corona which lies north of the Long Island Railroad and, after passing under Flushing creek as a siphon, will join the main sewer at the corner of Broadway and Lawrence Street, Flushing.

Most of College Point will be drained by two trunk sewers, one of which will tunnel through the hill from the foot of Fifth Avenue, while the course of the other will be along the shore, serving the westerly and northerly portions of College Point.

After considerable study, it has been found feasible, with the street grades as established, and with the main sewer at reasonable depth, to collect practically all the sewage to Tallman Island without pumping. Some of the low land near the head of Flushing creek is so far from the main trunk sewer that its sewage will have to be pumped to that sewer.

At Tallman Island the sewage, after passing through grit chambers and coarse screens, will be pumped into the treatment tanks to be installed there. The clarified effluent will be discharged into the East river through submerged outlets at a considerable distance from shore.

Favorable conditions exist for the future relief of the main trunk sewer in this sub-division. This is fortunate, as the territory is very large, the main sewer long, and the present population scattered and comparatively small. The trunk sewers which will join the main sewers, and the main sewer itself west of Elmhurst, have been designed to serve populations which are not likely to be exceeded for many years.

A future relief sewer designed to start on the Queens Boulevard at Caldwell Avenue, southeast of Elmhurst, and run in an easterly direction, relieving the main trunk sewer of practically all the sewage which will flow into it from the south between Caldwell Avenue and Mill creek. This relief sewer will cross Flushing creek near Strong's Causeway and enter a pumping station to be built near the confluence of Mill and Flushing creeks. The Mill creek valley sewer will also be diverted so as to enter the station.

From the pumping station near the junction of Mill and Flushing creeks, the sewage will be lifted into a high level relief sewer which will flow through Flushing and follow the high land west of Whitestone to the treatment works at Tallman Island. This future high level intercepting sewer will be continued, above its junction with the force main from the pumping station just mentioned, in a southerly and easterly direction through Flushing, Ingleside, and Flushing Heights. The sewage from the high land between the Mill creek valley and Cedar Grove Cemetery may be collected and siphoned across the lower end of this valley into the high-level sewer in Flushing.

The high-level relief sewers, just described, will deliver by gravity to the treatment works the sewage from practically all the high land of the Corona-Flushing Sub-division which lies east of Flushing creek.

The original main trunk sewer from Winfield to Tallman Island will be of sufficient size to carry the sewage which, for many years, may be expected to originate within the territory which will not be served in the future by the relief sewers, as described. It will be large enough, moreover, to carry the sewage from the whole Corona-Flushing Sub-division for a long time.

Collecting Sewers for the Northeastern Queens Sub-division.—The sewage from the Northern Queens Sub-division will be carried to Cryder's Point by two main intercepting sewers. One of these, the Whitestone intercepting, will start near the water west of Whitestone Point and run along the Whitestone shore and through Beechhurst to Cryder's Point. Near Whitestone Landing, a trunk sewer, draining a large inland district between Whitestone and Ingleside, will join the intercepting sewer.

The other main intercepting sewer will extend along the shores of Little bay and Little Neck bay, from Cryder's Point to a point in Bayside just north of Oakland Lake. At this place a trunk sewer will extend to the west, draining the large district between Ingleside and Bayside. At Broadway, in Bayside, the sewage from Douglaston, Little Neck, and the low land lying between Bayside and Douglaston, will be received into the main intercepting sewer through a force main which will run from an automatic, electrically-operated pumping station near Alley creek. To this pumping station the sewage from Douglaston and Little Neck will be brought by an intercepting sewer starting east of Douglas Manor and following closely the shore of Little Neck bay to the pumping station.

16 Practically all the sewage of the Northeastern Queens Sub-division, with the exception of that from Douglaston, Little Neck, and the low lands around Alley creek, can be brought to Cryder's Point, and there passed through screens and discharged into deep water by gravity. The sewage from a very small area near Whitestone Landing, and from several low-lying districts along the shore of Little bay and Little Neck bay, will have to be pumped into the high level sewers when the population on these areas becomes large enough to require sewage facilities. Also, a small marshy district near the city boundary, east of Douglas Manor, cannot be drained into the Douglaston intercepting sewer. These small districts will be served by inexpensive automatic pumping stations.

All the trunk and intercepting sewers of this sub-division, excepting the lower end of the intercepting sewer from Bayside to Cryder's Point, have been designed to serve a population which is not likely to be exceeded for many years. From Shore Avenue northward, it is proposed to relieve this sewer by a parallel sewer run-ing to Cryder's Point, but such a relief sewer will not be necessary for a long period.

Areas, Populations and Quantities of Sewage.

The following table gives, for the several sub-divisions, the areas, the estimated population and average dry-weather sewage flow upon which the design of the sewers was based, and the capacities of treatment works which the Commission has used as a basis for estimating the cost of the projects proposed for the Upper East River and Harlem Division:

Sub-division.	Area (without parks, etc.), acres.	Population.			Average dry-weather flow of sewage Mgd.		Capacity on treatment works on—	
		In 1910 from U. S. census.	In 1940 (estimated).	Which sewers are designed to serve.	In 1910.	In 1940.	Which sewers are designed to carry.	Which estimate is based Mgd.
Harlem	12,100	905,300	2,105,800	2,838,000	124.4	302.2	404.6	200
Eastern Bronx	10,600	30,300	73,000	.....	3.8	12.8	.....	20
Northwestern Queens	3,100	10,000	28,500	253,000	0.5	5.0	34.0	15
Corona-Flushing	16,800	62,200	179,800	282,400	4.0	27.5	39.0	40
Northeastern Queens	5,900	8,000	22,900	62,800	0.3	4.5	9.6	10
Totals	48,500	1,106,800	2,410,000	.....	133.0	352.0	.....	285

17 Preliminary Estimates of Cost of Main Drainage Works.

The following table gives a summary of the estimated cost of construction and of the annual charges for maintenance and operation for the works suggested in this report. The costs of land and rights of way are not included.

Sub-division.	Cost of construction, including engineering.	Cost of maintenance and operation, including fixed charges.
Harlem	$9,814,000	$701,000
Eastern Bronx	708,000	87,000
Northwestern Queens	352,000	29,000
Corona-Flushing	1,961,000	154,000
Northeastern Queens	563,000	42,000
Total	$13,398,000	$1,013,000

Executive Secretary.

Preliminary Reports on the Disposal of New York's Sewage.

V.

Study of the Collection and Disposal of the Sewage of the Richmond Division.*

Metropolitan Sewerage Commission of New York.

George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sooysmith, Linsly R. Williams, Commissioners.
September, 1912.

1 *Study of the Collection and Disposal of the Sewage of the Richmond Division.*

September 1, 1912.

Honorable William J. Gaynor, Mayor of the City of New York:

SIR: This report on the collection and disposal of the sewage of the Richmond Division, is the fifth in the series of Preliminary Reports on the Disposal of New York's Sewage which has been issued by this commission with the object of making public at an early date its opinion as to the way in which it will be necessary to deal with the sewage of the Metropolitan District.

The adoption of the plans here proposed would provide the northern and northeastern parts of Staten Island, containing all the more thickly settled localities and including over eighty per cent. of the population of the borough, with main drainage and sewage disposal works at moderate cost, and would afford as great a measure of protection as a consideration of the condition of the water in the whole harbor and of the possibilities of contamination in this locality seem to make necessary.

The disposal of the sewage of that part of the Borough of Richmond not provided for in this report offers little difficulty. That part of the territory which is not rural should be provided with local

* This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service. Some features of this report will remain open for revision until the final report is submitted.

disposal plants of such high efficiency that their effluents can be discharged into the neighboring water courses without danger of causing local offense.

The possibility that a greater degree of protection for the harbor than is proposed in this report may be needed in the distant future has been borne in mind in preparing these plans and, in consequence, the works have been so devised as to be adaptable to a more comprehensive scheme without undue loss of the completed structures.

All the work planned in this report will not be required in the immediate future, but it is regarded as necessary that such main drainage work as is undertaken by the city in this borough shall conform to these plans or such modifications of them as a more detailed study of the local conditions than has been possible by this commission may require.

To a great extent the sewerage plans made by the local authorities have been utilized in preparing the plans of main drainage and disposal described in this report, the object being to aid and supplement the city's efforts in disposing of the sewage in a sanitary manner. In those localities for which the borough has had no definite sewerage plans, it has been necessary to outline the future lateral sewerage districts as seemed most reasonable from the information at hand concerning the proposed locations and grades of streets. By following the same outlines as nearly as may
2 seem best after detailed study, the engineers of the borough will be able to facilitate the final design of the main drainage systems along the lines recommended in this report.

General Description of the Territory.

Location and Area.—This report deals with that part of Staten Island which slopes toward the Narrows, Upper bay, Kill van Kull and Newark bay, or nearly the whole of the northern and northeastern portions of the Borough of Richmond. This territory includes, besides the natural drainage areas tributary to the bodies of water mentioned, a comparatively small area which drains naturally to Willowbrook, and thence to Fresh Kills and Lower New York bay, and from which it is feasible and desirable to carry the house sewage to the Kill van Kull for final disposal.

The line bounding the district on the south starts from Fort Wadsworth at the Narrows, and runs in a generally westerly direction through Arrochar and Grasmere, across Todt Hill and through the grounds of the Richmond Borough Almshouse, finally reaching the village of New Springville. On the west the boundary line follows closely the Port Richmond Road, passing through Bull's Head and Graniteville, and thence not far from Morningstar Road to a point south of Elm Park, from which point it follows the watershed along the Staten Island Rapid Transit Railroad, westerly nearly to South avenue, whence it runs in a northwesterly direction, crosses Richmond Terrace near Holland avenue, and continues to the shore of Newark bay east of Howland Hook.

Between this line and the established bulkhead line bordering the Narrows, Upper bay, the Kill van Kull and Newark bay, there is included an area of 9,178 acres, or about 14.3 square miles exclusive of cemeteries, parks, institutional property, U. S. Government land, etc. This area is approximately equal to one-fourth of the total land surface of Staten Island.

Topographical Features.—The topography of the territory is varied. The part which drains to the northeastern shore of Staten Island is separated from that which drains to the north shore by a high ridge which traverses the island in a general northeasterly and southwesterly direction, and which rises at Todt Hill, on the southern boundary of the territory, to an elevation of 409.8 feet above the Richmond high water datum. The slopes on the easterly side of the ridge, within the limits of the territory, are precipitous. The westerly and northerly slopes are generally gradual.

In the western part of the territory the land is comparatively low, and in many places, near the water courses and shores, it is
3 swampy. The slopes down to these swampy areas are generally gradual, and the ridge marking the outline of the district on the west is not high.

The terminal moraine forms a conspicuous feature of the topography in the southeastern part of the district. Along the boundary line from Arrochar to Grasmere the bare rounded hills and numerous depressions and ponds, characteristic of morainic topography, are especially noticeable.

The land near the shore, from Fort Wadsworth to Howland Hook, is made up alternately of headlands, of varying height, and valleys. Streams flow through many of these valleys, while in others the natural water courses have been replaced by sewers. Much of that portion of the territory which drains to the Kill van Kull lies within the drainage area of Bodine creek, which is the largest water course in the district.

Population.—Nearly all the more thickly settled part of Staten Island lies within the drainage districts of the Narrows, Upper bay, Kill van Kull and Newark bay. Out of a total population in the Borough of Richmond, in 1910, of 85,969, this territory contained an estimated population of 64,320, or almost exactly three-fourths of the total. In 1940, it is probable that this area will have no less than 140,000 people out of 190,000, the minimum number that may be expected in inhabit the borough at that date.

While, for a number of years previous to 1905, the growth of population in the borough was slow, due to various causes, since that date the population has increased at a comparatively rapid rate. Owing to changed conditions, it seems reasonable to expect that this rapid growth will continue.

Development.—The land which lies near the shore from Rosebank almost to Howland Hook is well populated, and in some places thickly settled, but no part of the whole area has a population closely approaching in density that which exists in most of the other boroughs of New York City. In fact, with the exception of a few centers which are chiefly devoted to business purposes, and a number

of spots where buildings of a poor class are huddled together, the whole area, for a considerable distance back from the waterfront, may be termed suburban. Further from the water, most of the territory is rural in character, and there are large tracts which are still wholly unimproved.

While the populated sections will gradually extend farther and farther from the waterfront, much of the territory to the south and southwest is likely to remain in a rural and unimproved state for many years. It seems certain that the business centers will gradually expand, although nearness to Manhattan will cause activities to be confined mostly to the establishment of stores to supply the needs of the local population. In course of time docks
4 and warehouses will undoubtedly occupy the Stapleton waterfront, and water and rail facilities make the north shore a superior place for the establishment of factories.

Sewerage of the Territory.—During the last few years, large amounts of money have been spent by the borough in the construction of sewers. In the areas which drain to the Narrows and Upper bay, and along the western part of the north shore of the island, much progress has been made in replacing old and shallow village sewers, formerly built to take care of the immediate needs for house drainage, by modern systems. Except in some of the low areas near the waterfront, these new sewers are of the combined type.

In much of New Brighton, and in West Brighton and Port Richmond, the old village sewers have so far remained more or less adequate to the needs of the communities. Few, if any, new combined sewers have been constructed, and little has yet been done concerning the preparation of drainage plans for these areas. The natural water courses which traverse those areas have proved sufficient for the removal of the storm water, and they can continue for some time to perform this service for many places. Certainly, if the storm water in the thickly settled areas near the waterfront is removed by sewers, the run-off from the more sparsely settled upland territory can be adequately provided for in the natural water courses for many years to come.

Wherever new and complete systems of sewers have been installed, the dry-weather flow has been diverted from them, above mean high tide, and carried in a pipe to moderately deep water and the outlet for the storm water has been placed near the shore line. It is the intention of the borough authorities to extend the dry-weather and storm-water outfalls to the pierhead and bulkhead lines, respectively, when the piers and bulkheads are built. By this method of discharging the house sewage into deep water, during dry weather, the shores near the sewer outlets have escaped much of the pollution which otherwise would have been inevitable. Nevertheless it is felt that, at many points, the discharge of house sewage in a crude state, even at the pierhead line, will not be permissible much longer. For this reason an experiment station has been established by means of which the most suitable method of handling the local sewage disposal problem can be studied.

Separation of the Territory into Subdivisions.

The topography of the whole division is unfavorable for the collection of all the sewage to one central point for disposal. The high ridge separating the areas draining to the northeastern shore of the island from those draining to the north shore, the small areas of low land in the western end of the division, the great distance which it would be necessary to carry much of the sewage and the amount of pumping required are opposed to the collection of the sewage at a point near the Narrows, which is the most favorable place available for its ultimate discharge.

While the discharge of all the house sewage from the northerly and northeasterly slopes of Staten Island into the Narrows would be desirable, and economy of operation would result from having only one disposal plant to maintain, it is believed that the benefits derived would not compensate sufficiently for the cost of carrying the sewage to such a plant. Moreover, it seems certain that the Kill van Kull, with its deep water and swift currents, would provide, for many years, if not for all time, a sufficiently favorable place for discharging the sewage from the areas bordering on Newark bay and the Kill van Kull, after it has been passed through settling tanks.

The territory with which this report deals has been subdivided in such a way as to facilitate the collection of the sewage, to provide for each subdivision a favorable and adequate place for treatment works, and to minimize the amount of pumping necessary. At the same time care has been taken not to divide the territory to such an extent as to cause the establishment of plants too small to be operated economically.

The subdivisions, five in number, have been given names associated with the points chosen for the sites of the respective treatment works. They are named and described as follows:

1. The Quarantine Subdivision comprises the area naturally draining to the Narrows from Fort Wadsworth to the Marine Hospital, Stapleton. The settlements known as Clifton, Rosebank and Fort Wadsworth lie within its boundaries.

2. The Stapleton Subdivision comprises the area naturally draining to the Narrows between the Marine Hospital and St. George. Tompkinsville, Stapleton and Concord lie within this area.

3. The Livingston Subdivision comprises the area naturally draining to Upper New York bay west of St. George, and most of that draining to the Kill van Kull east of a line joining the southerly end of Silver Lake, the corner of Castleton and Bement avenues, and the northerly end of Elm Court, West New Brighton. Sailors' Snug Harbor and the settlements of New Brighton and Livingston are included.

4. The West New Brighton Subdivision comprises, roughly, the area naturally draining to the Kill van Kull between the westerly limit of the Livingston subdivision and Tower Hill, Port Richmond, together with the area draining to Willow brook, east of Port Richmond Road. West New Brighton and Castleton Corners, and parts of Port Richmond, Graniteville, Bull's Head and New Springville are in this subdivision.

5. The Elm Park Subdivision comprises, roughly, the area naturally draining to the Kill van Kull and Newark bay between Tower Hill and Holland avenue. Elm Park and parts of Port Richmond and Mariner's Harbor are within its confines.

The boundaries of the Quarantine, Stapleton and western part of the Elm Park subdivisions, are fixed by the limits of the sewerage districts already outlined by the engineers of the borough; but the boundaries of the Livingston and West New Brighton subdivisions, except where bordering on the Stapleton subdivision, and of the eastern part of Elm Park subdivision, have been placed by this commission as seemed best suited to the main drainage plans to be worked out. The limits agree, however, in a general way, with sewerage districts which have been outlined, but as yet only approximately, by the engineers of the borough.

Outline of the Proposed Plan for Main Drainage.

The proposed plan for the Quarantine subdivision provides for the collection of the sewage by a high-level intercepting sewer to the foot of Nautilus street, near the Quarantine Station, where, after passing through coarse screens, grit chambers and fine screens, it will be discharged into the deep water of the Narrows. The sewage from the low land in Clifton will be pumped to the high-level sewer.

In the Stapleton subdivision, the sewage will be collected near the foot of Water street, Stapleton, by high- and low-level sewers, passed through settling tanks, and discharged into the Narrows, off Canal street.

The plan for the Livingston subdivision provides for the collection of the sewage, mostly by high-level sewers, to the waterfront at Kissel avenue, Livingston, where, after being passed through settling tanks, it will be discharged into deep water in the Kill van Kull.

According to the proposed plan, the sewage from the West New Brighton subdivision will be brought, by high- and low-level intercepting sewers, to the waterfront near the garbage incinerator in West New Brighton, passed through settling tanks, and discharged into deep water in the Kill van Kull.

7 In the Elm Park subdivision, the sewage will be collected, by high- and low-level sewers, to the vicinity of Newark avenue and Richmond Terrace, where, after being passed through settling tanks, it will be discharged into deep water in the Kill van Kull.

The sewers will vary from 8 inches to 6 feet 9 inches in diameter, and their total length will be 10.88 miles.

Main Drainage Systems.

Kind of Sewers Proposed.—The collecting and intercepting sewers, as planned for the five subdivisions, are designed primarily to carry eventually only the dry-weather flow from the contributing sewers, already built or to be built, in these subdivisions. Attention has been directed to the fact that the sewers built by the borough have

been, in general, of the combined type, and that future construction is planned along the same lines. This means that during wet weather much of the house sewage, mixed with varying volumes of storm water, will continue to the bulkhead line without being intercepted, and will there be discharged. The growth of population to be expected in the borough has so influenced the design of the proposed dry-weather trunk sewers that many of them will assist materially, for a considerable period, in the disposal of the storm water.

While it would be inadvisable, in those districts that have already been sewered by the borough authorities, to provide systems of separate sewers, using those already built to remove storm water, this commission considers it desirable, from now on, to construct sewers on the separate plan, and provide only such storm-water sewers as are demanded from time to time. Relieved of an admixture of house sewage, it is likely that many of these storm sewers might empty directly, for many years to come, into the natural water courses which flow northerly into the Kill van Kull. The building of the comparatively small sewers required for the house drainage, and only such storm-water sewers as are absolutely needed, would minimize the cost of sewer construction, a consideration of much weight, especially in view of the fact that the population which can be assessed is small. Among other advantages which the separate system would possess may be mentioned better protection against pollution to the water near shore during wet weather and less quantity of sewage to be handled in the treatment works.

The plans here proposed have been worked out on the assumption that the present policy of constructing combined sewers will be continued, but whether or not this policy is followed in the areas to be sewered in future, the principal features of the main
8 drainage systems and of the treatment works would be the same. If the sewers were built on the separate system, however, connecting chambers, overflows, tide-gates, and perhaps grit chambers, would be unnecessary, and the costs would be reduced to that extent.

Population and Quantity of Sewage.—The sizes to be provided for the main trunk sewers for collecting the dry-weather flow in localities similar in position and condition to the settlements on the northern and northeastern shores of Staten Island should not depend, as has been the case in many cities, upon an estimate of population at any definite period, but upon densities of population on the tributary drainage areas which are considered probable when the areas shall have reached approximately their ultimate development.

The part of Staten Island included within this division is so near Manhattan, and there are so many other reasons, including the possibility of rapid transit, which may greatly accelerate the growth of population in any part of or throughout the district that it would be unwise to restrict the capacities of the proposed trunk sewers to suit what now appears to be the needs of the district thirty years hence. The total construction cost of the sewers as designed will not be a very large sum, and the saving effected by cutting down

their capacities materially would not be as great as might be supposed.

In order to estimate the necessary capacities of treatment works, pumping equipment and other parts of the main drainage works that can easily be added to at later periods, it is essential that estimates be made of present populations and sewage flows. The following table presents these figures as estimated for the various subdivisions for the year 1910, based on United States Census figures. The areas of the subdivisions are calculated to the established bulkhead line, but do not include cemeteries, parks, Sailors' Snug Harbor, U. S. Government property, etc. The "area sewered" column of the table has no reference to the actual area in each subdivision that was provided with sewers in 1910, but the figures represent roughly the areas that were fairly well settled and might with reason be provided with sewers. The populations estimated for these sewered areas are the ones which have been used as a basis for estimating the flow of house sewage. It will be noticed that in the low-level areas the whole population was assumed to be served by sewers. The total sewage flow, manifestly, is not the average daily amount of sewage that was discharged from the sewer outlets of the district during dry weather, in 1910, but the figures represent a rough estimate of the average amount that might have been expected under a more complete development of the sewerage systems.

Here, as throughout this report, the average flow of house sewage has been assumed to be 125 gallons per inhabitant per day,
9 and the average ground-water leakage has been taken at 500,000 gallons per square mile per day, irrespective of local conditions.

Population and Sewage Flow of the Five Sub-divisions in 1910.

1.—High Level Territory.

Sub-division.	Area, acres.	Area sewered, acres.	Population.	Population on sewered area.	House sewage, mgd.*	Ground water leakage, mgd.*	Total sewage flow, mgd.*
Quarantine	661	330	6,057	5,500	0.69	0.26	0.95
Stapleton	1,532	600	16,152	15,000	1.40	0.47	1.87
Livingston	893	600	11,183	10,000	0.93	0.47	1.40
W. New Brighton	4,735	600	12,400	10,000	0.93	0.47	1.40
Elm Park	173	140	3,589	3,500	0.33	0.11	0.44
Totals	7,994	2,270	49,381	44,000	4.10	1.78	5.86

* Million gallons per day of 24 hours.

2.—High Level Territory.

Quarantine	156	80	1,404	1,404	0.13	0.06	0.19
Stapleton	182	110	3,241	3,241	0.30	0.09	0.39

Elm Park.....	632	420	8,542	8,462	0.79	0.33	1.12
Totals.....	9,178	3,015	64,320	58,939	5.49	2.37	7.86

* Million gallons per day of 24 hours.

10 The following table gives the densities of population, total population and average sewage flow used in designing the sewers of each subdivision. All the territory is assumed to be sewered. The area as far as the bulkhead line has been assumed to be populated. Much of the ground near the water will be occupied by industrial establishments instead of dwellings, but sufficient allowance for the sewage flow from these has probably been made by assuming the area populated throughout.

Total Population and Sewage Flow used in Designing the Proposed Sewers.

Sub-division.	Density of population per acre.	Population			Aver. sewage flow mgd.*		
		High level.	Low level.	Total.	High level	Low level.	Total.
Quarantine	75 –100	52,870	15,600	68,470	7.12	2.08	9.20
Stapleton	70†–150	112,385	19,870	132,255	15.24	2.63	17.87

* Million gallons per day of 24 hours.
† Average density on 1,116 acres.
‡ Average density on 1,814 acres. Average density of 50 on 1,283 acres.

Collecting Sewers for the Quarantine Subdivision.—Most of the sewage of the Quarantine subdivision will be collected at the foot of Nautilus street by a high-level intercepting sewer which will intercept the dry-weather flow from the combined sewer in Maple avenue at the corner of Anderson street and pass through Anderson street, Chestnut avenue, New York avenue, Sylvaton terrace and Bay street, and along the shore to Nautilus street. On its route, it will receive the flow from all the territory lying south and west of its course.

The sewage from the low land in Clifton will be collected at the corner of Bay street and Maple avenue by an intercepting sewer in Bay street which will intercept the dry-weather flow from existing sewers in Norwood avenue and Simonson avenue. At Bay street the dry-weather flow from the Maple avenue sewer will be diverted, and together with the flow from the Bay street intercepting sewer will be

led into an automatic, electrically-operated pumping station to be located at this corner. From this pumping station, the sewage will be pumped through a force main in Bay street to the high-level intercepting sewer at the corner of Bay street and Sylvaton terrace.

11 The dry-weather flow from the existing Nautilus street sewer, which drains a large area, will be intercepted and carried by a short connecting sewer to a junction with the high-level sewer above mentioned. The plan also contemplates the construction of a small high-level sewer in Centre street which will intercept the dry-weather flow from the combined sewer at the corner of Norwood avenue and discharge it at Simpson avenue, or a short distance north of it, into the combined sewer planned for Centre street. It will thence be carried to the Maple avenue sewer and finally into the high-level sewers in Anderson street.

The proposed collecting sewers in the Quarantine subdivision vary from 12 inches to 3 feet 3 inches in diameter. Their total length, including the force main, but exclusive of the outlet pipe, is 1.46 miles.

Collecting Sewers for the Stapleton Subdivision.—A large part of the area included within the Stapleton subdivision is at a sufficient elevation to permit its sewage to be collected and passed by gravity through tanks located at Stapleton, but the elevations of the streets in the vicinity of the works are so slight that the sewage from the high-level districts will have to be carried to the works in long conduits submerged below the hydraulic gradient.

On the north, the dry-weather flow from the Arietta street sewer will be intercepted at Stuyvesant place and brought, together with sewage collected on its route, by a high-level sewer passing through Stuyvesant place, Griffin, Hannah, Sarah Ann, Van Duzer and Elizabeth streets to a point a short distance east of Van Duzer street, from which place it will be carried to the treatment works, located on Front street between Prospect street and Water street, by a siphon passing through Elizabeth street, rights of way and Front street.

On the south, the dry-weather flow from the large sewer in Board street will be intercepted at the corner of Canal and Board streets and carried to the treatment works by a siphon passing through Canal, Water and Front streets. From the corner of Riker and Broad streets, a connection will be laid in such a way as to join the large Broad street sewer just above the point at which its dry-weather flow is intercepted.

At Wright and Beach streets, this siphon will have connections through which the dry-weather flow from the existing sewers in these streets will be added. Ample head for this purpose can be secured without making these cutoff sewers of great length.

That part of the sewage of the subdivision which cannot be passed through the treatment works by gravity will be brought to an automatic, electrically-operated pumping station located at the works. Here the sewage will be raised by the pumps to such an elevation as to allow it to pass through the tanks.

12 The two low-level intercepting sewers required will be built in Front street and will be short. The one from the north

will start, until its extension is required, by intercepting the dry-weather flow from the existing Elizabeth street sewer: the one from the south will intercept the dry-weather flow outlet sewer at present in Canal street, and will be joined by the existing 15-inch sewer in Water street. It is assumed that the 10-inch sewer in Thompson street, which now creates foul conditions by discharging into the dock, will be joined to the sewer in Canal street and the flow thus taken to the treatment works.

In designing the high level siphons, the available head was found so small that the velocities through the siphons would have to be less than desirable. They would be especially small for a number of years. Trouble from this cause can be obviated by constructing by-passes from these siphons to the suction well of the pumping station at the treatment works. By means of these by-passes, the siphons can be easily and effectively flushed.

It was found best to make the south siphon of a capacity sufficient to take care of the needs for only a few years with the idea that one or two more conduits can be constructed as required. With the north siphon, conditions were somewhat different. It will be economical to provide this siphon with the same capacity as that of the intercepting sewer leading to it. In order to make the velocity of sewage as great as possible when the flow is small, the north siphon will consist of two pipes of different sizes, the larger one to come into use automatically when the level of the sewage in the high-level sewer reaches a certain height.

Both the north siphon, of 24-inch and 18-inch pipes, and the south siphon, of 24-inch pipe, could it is thought, be built economically and properly of vitrified pipe, with bituminous joints and surrounded by concrete, and the estimates have been based upon this type of construction.

The proposed collecting sewers in the Stapleton subdivision vary from 15 inches to 2 feet 9 inches in diameter. Their total length, including siphons, but exclusive of outlet pipe, is 1.54 miles.

Collecting Sewers for the Livingston Subdivision.—Practically all the sewage of the Livingston subdivision can be brought to the treatment works at the foot of Kissel avenue and passed through them by gravity.

The sewage from St. George and New Brighton will be collected by a high-level intercepting sewer which will start at the corner of Jay and Wall streets and pass through Jay street and Richmond terrace to the treatment works.

From the south a high-level sewer will start at the corner of Kissel avenue and Brighton boulevard and pass through Kissel and
13 Bergen avenues and Health place to the treatment works.

A branch of this sewer will be constructed in Bergen avenue between Oakland avenue and Health place.

A small low-level intercepting sewer will be built in Richmond terrace from Oakland avenue to a small, automatic, electrically-operated pumping station located at the site of the treatment works.

In this subdivision the high-level sewers will have to pass through low land before reaching the treatment works. The street grades

in these low areas have been at least tentatively established. However, the area is not yet built up and it will be feasible to raise the projected street grades wherever necessary, so as to give a light, but sufficient cover over the top of the sewers.

The proposed collecting sewers in the Livingston subdivision vary from 10 inches to 3 feet 3 inches in diameter. Their total length, exclusive of outlet pipe, is 2.77 miles.

Collecting Sewers for the West New Brighton Subdivision.—The sewage of the West New Brighton subdivision will be collected by two high-level and two low-level sewers. Just before reaching the treatment works, which are to be located south of Starin avenue, between Bodine and Dongan streets, the sewers join so as to form one high-level and one low-level sewer.

The east high-level intercepting sewer will start at the corner of Elm court and Henderson avenue and pass through Henderson avenue, Water street and Richmond terrace to a junction with the west high-level intercepting sewer.

The west, or perhaps better, the south-high-level intercepting sewer, has been assumed, for the purposes of this report, to start at the proposed Northfield boulevard. Its route will be through Linnet street, Madison avenue, Jewett avenue, Roberts street, Manor road, Castleton and Columbia avenues, Cedar and Bodine streets and Richmond terrace, and thence through the city's property at the West Brighton garbage incinerator. A small branch of this sewer will be built in Palmer avenue east from Heberton avenue, so as to intercept the sewage flow from the high area west of the latter street.

The east low-level intercepting sewer will start at the foot of Broadway, at which point it is assumed that the flow from the combined sewers in the low area in the vicinity will collect, and will pass through Richmond terrace and Starin avenue to Dongan street, where it will join with the west low-level intercepting sewer.

The sewage from a large part of Port Richmond and the low area in the vicinity of Bodine creek and Palmer's run will be brought to an automatic, electrically-operated pumping station at the treatment works by the west low-level intercepting sewer which
14 will start in Richmond avenue north of Richmond terrace and pass through Richmond terrace, Starin avenue and Dongan street.

Whether the large undeveloped areas in the West New Brighton subdivision, which lie south of the proposed Northfield boulevard, are finally sewered upon the separate or upon the combined plan, all the dry-weather sewage flow can be brought by gravity to the upper end of the west high-level intercepting sewer as proposed.

On account of the large population which eventually will occupy the extensive area tributary to it, this sewer is much larger than any of the collecting sewers in the other subdivisions, and can serve for many years to carry to the waterfront much of the storm-water brought to it by the combined sewers in West New Brighton. The surplus storm-water would be led to a trunk sewer which would also collect the flow from the sewers of the low-level district. It is suggested that this trunk sewer be designed of a size sufficient to care for the ultimate

dry-weather flow of the low-level district tributary to it, together with only such storm water as it would probably have to carry for a few years, with the idea that later, when it becomes necessary to close up the water courses and provide artificial channels for the storm-water from the large and now undeveloped areas, a large storm-water sewer can be built to the waterfront.

The conditions in much of this subdivision, with its numerous open water-courses, are such that great economy would result from the construction of sewers on the separate system. It will be particularly desirable, when the time arrives, to sewer on the separate system that portion of this subdivision which lies south of Richmond turnpike and drains directly to Willow brook. When it becomes no longer possible to provide for the storm-water from this area on the surface, it should be emptied into Fresh Kills instead of being carried with the house sewage all the way to the Kill van Kull.

In all the subdivisions, it has been assumed that streets would be opened and graded according to the plans at present outlined by the borough. In this subdivision particularly, the routes of many of the proposed sewers are laid out in streets which are not yet opened.

Owing to topographical conditions in the different subdivisions, the high-level sewers, near their entrance to the various treatment works, have had to be placed lower with reference to the ordinary sewage level in the settling tanks than is desirable. With the small amount of sewage that will be carried through these sewers in dry weather for some time after their construction, small velocities will occur in their lower ends. This will cause trouble from deposits only for a short distance, if at all, in any of the sewers except the west high-level sewer of the West New Brighton subdivision, as all of
15 them except the one named are small in size and their grades are considerable. While the dry-weather flow is small it might be practicable to run the tanks with a somewhat lower sewage level than that for which they are designed. Opportunity for creating a greater velocity at intervals might be afforded by a temporary lowering of the water level in the tanks or by providing a by-pass to the pumping stations, outfall pipes, or to storm or combined sewers at a lower level.

The proposed collecting sewers in the West New Brighton subdivision vary from 8 inches to 6 feet 9 inches in diameter. Their total length, exclusive of the outlet pipe, is 3.14 miles.

Collecting Sewers for the Elm Park Subdivision.—In the four subdivisions already considered, it has been found practicable to collect and dispose of most of the sewage by gravity. Conditions in the Elm Park subdivision are different, resulting in the necessity of pumping considerably more than half the sewage.

A high-level intercepting sewer will start at the corner of Lafayette avenue and Harrison avenue, Port Richmond, to which point it is assumed that a combined sewer in Elizabeth street and Harrison avenue will bring sewage from points as far east as Broadway. The route of the high level sewer will be through Harrison, Nicholas and Charles avenues, Douglas street and Newark avenue to the treatment works at the corner of Newark avenue and Richmond terrace.

A short branch of this sewer in Roselle and Monroe streets, as far as the railroad, will bring to it the dry-weather flow from existing sewers in Monroe and Cedar streets.

From the east, the sewage from the low-level district will be brought to an automatic, electrically-operated pumping station at the treatment works by a sewer in Richmond terrace starting at Nicholas avenue. From the west, the sewage will be carried to the pumping station by a sewer in Richmond terrace. This sewer will intercept the dry-weather flow from the existing combined trunk sewers in Harbor road, Union avenue and Housman avenue.

The proposed collecting sewers in the Elm Park subdivisions vary from 8 inches to 3 feet in diameter. Their total length, exclusive of the outlet pipe, is 1.97 miles.

Pumping Stations.—All the pumping stations in the division will be of the automatic, electrically-operated type. The current for operating them can be purchased, or it might be furnished by the garbage incineration plants at West New Brighton and Clifton, thus affording a desirable outlet for some of the surplus power generated at those plants. This surplus power would undoubtedly be used at the West New Brighton sewage pumping station, as there would be no expense for transmission at this point. It would also probably pay to transmit power from the Clifton incinerator to the Maple avenue pumping station in the Quarantine subdivision. Whether it would be economical to transmit power from the West New Brighton incinerator to the Elm Park and Livingston pumping stations, and from the Clifton incinerator to the Stapleton pumping station, would depend upon the price for which current could be purchased from the light and power company.

16

All the pumping equipment ultimately necessary in these stations would not be required at first. However, all pumps and motors should be in duplicate.

The following table gives the average total head pumped against, the estimated average sewage flow which would have arrived at each pumping station in 1910 under the assumptions given in the discussion of population and sewage flow, the average sewage flow at each station which was used as a basis for estimating the cost of operation, and the aggregate average sewage flow which the sewers leading to the station were designed.

Pumping station.	Total head, feet.	Average sewage flow—Mgd.*		
		Estimated for 1910.	Basis for cost of operation.	Contributing sewers designed for.
Maple Avenue....	10.0	0.19	0.50	2.08
Stapleton	12.0	0.39	1.00	2.63
Livingston	14.0	0.06	0.25	0.88
W. New Brighton..	13.5	0.66	2.00	5.04
Elm Park.....	14.5	0.68	2.00	5.37
All Stations.....	....	1.98	5.75	16.00

* Million gallons per day of 24 hours.

Outlets.—All the outlet pipes through which the effluent from the various treatment works will be discharged will extend into deep water where the currents are swift.

In the Quarantine subdivision, it is proposed to make use of an existing 20-inch cast-iron outlet sewer which extends out to a point about 225 feet from the present shore line. This pipe will be of sufficient capacity to last for many years, and it should be extended to, or nearly to, the pierhead line. When necessary, another outlet pipe can be added.

17 There is at present a 3-foot wood stave pipe running to the outer end of the municipal ferry pier at the foot of Canal street, Stapleton, through which pipe the dry-weather flow from the tributary sewers is carried to deep water. This pipe is of sufficient size to carry the effluent from the proposed Stapleton treatment works for many years, and could be made of use. When the pier is extended to the established pierhead line, the outlet pipe should be extended also. When necessary, another outlet can be built at the foot of Prospect street.

From the Livingston treatment works, it is proposed to lay a submerged 24-inch cast-iron pipe to deep water beyond the pierhead line and, when necessary, another outlet pipe can be laid.

Although greatly increased capacity of outlets from the West New Brighton treatment works will ultimately be needed, a 3-foot pipe will be ample in size for a long time. It would probably be practicable to lay a wood-stave pipe under the existing pier at the foot of Bodine street and to extend the outlet for some distance into deeper water by means of a submerged cast-iron pipe.

From the Elm Park treatment works, it is proposed to lay a submerged 20-inch cast-iron pipe into deep water at a considerable distance beyond the pier-head line. This pipe will be of sufficient size to last for a number of years. It can be supplemented by another pipe when greater capacity becomes necessary.

Treatment Works.

Forms of Treatment Proposed.—The form of treatment proposed for the sewage is coarse screening and sedimentation, and is the same for all the subdivisions except the Quarantine. A period of from two to three hours should be allowed for settlement. It is believed that the deep water and strong currents along the shores of this district will afford ample opportunity for the diffusion and digestion of sewage in such quantities as may be expected from this portion of Staten Island, if it is treated in the manner proposed, and discharged from submerged outlets into water of 30 feet or more in depth and good current.

The successful protection of the water along these shores will, however, depend somewhat upon the measures taken elsewhere for the betterment of the harbor. The present pollution along the northern, and particularly the northeastern, shore of Staten Island is, to some extent, due to the condition of the harbor water in general.

Passage through grit basins, coarse and fine screens is the form of treatment proposed for the Quarantine subdivision, as the opportunity for diffusion and digestion of the sewage by the harbor waters is here especially favorable.

At the treatment works for all the subdivisions, grit chambers, with a settling period of from one to two minutes, will be
18 provided. Where screening is to be used, the grit chamber will prevent heavy deposits which might occur in the outlet pipes or on the harbor bottom near the points of discharge. Where settling tanks are to be used, the grit chambers will guard against trouble that would occur from the deposition of heavy solids in the tanks which are intended for the sedimentation of organic matters.

Sites for Treatment Works.—Many factors have affected the choice of sites for treatment works in the various subdivisions. Among the chief considerations have been the existence of undeveloped land of sufficient area for plants of the size which will ultimately be necessary, the location of these areas at such points as may be best suited to an economical collection of the sewage, this collection being accomplished, as far as possible, without the use of pumping machinery, proximity to any serviceable sewage outlets that might occur, and favorable location with respect to railroad facilities.

At the foot of Nautilus street, there is ample room for locating a screen and for the Quarantine subdivision.

The best site for the location of settling tanks for the Stapleton subdivision seems to be on the west side of Front street between Water and Prospect streets. This location is contiguous to the railroad, and the greater part of the site is occupied by an old asphalt plant and storage yard which is out of use and for sale. On the Water street front there are a few old tenements. By a judicious arrangement of tanks, it will be possible on the area available to treat all the sewage that is likely to reach this point. If, for any reason, the purchase of this land is deemed inadvisable, there are other unoccupied sites in the immediate neighborhood which probably could be obtained.

The proposed site for the Livingston treatment works is west of Kissel avenue between Richmond terrace, as it is to be re-located, and Livingston place. There may be opposition to the establishment of treatment works here, but it is the logical place for them and, if the tanks are properly operated, no offense should be created.

The best site for treatment works in the West New Brighton subdivision is near the garbage incinerator. Economy of operation should result from their location at this point. The block bounded by Starin avenue, Dongan street, Richmond terrace and Bodine street, seems to afford the best site for the works and has therefore been selected. There probably will be plenty of room within this area, even without including the lots bordering on Richmond terrace, to treat any volume of sewage which needs to be collected at this point.

In the Elm Park subdivision, the most favorable site seems to be

at the east corner of Richmond terrace and Newark avenue, although there is a considerable amount of unoccupied land in the
19 vicinity. A location much farther to the west would be inadvisable, if for no other reason than on account of unfavorable conditions which exist there for the discharge of sewage.

Capacities of Treatment Works.—In designing the treatment works, sufficient capacity should be provided to take care of the volume of sewage to be expected for a reasonable period in the future. Nevertheless, the tank capacity to be provided in the first installation should not exceed the economical limit, as units can be added when necessary.

The following table gives the estimated average daily amount of sewage which might have been brought to the various works had they been in existence in 1910, and also the capacities which were used as a basis for estimates of cost of construction and operation and which are deemed reasonable as capacities to be provided for in the first installations.

Sub-division.	Average sewage flow—Mgd.*	
	Estimated for 1910.	Treatment works, first installation.
Quarantine	0.96	3.0
Stapleton	2.26	6.0
Livingston	1.46	4.0
W. New Brighton	2.06	6.0
Elm Park	1.12	3.0
All Sub-divisions	7.86	22.0

* Million gallons per day of 24 hours.

Disposal of Sludge.—The sludge produced in this division may be disposed of in various ways. For many years the amount of sludge will be comparatively small. In 1910, the digested sludge from two-story settling tank installations in the four subdivisions for which they are proposed might have amounted to 18 tons a day. When the capacities of the first tank installations are reached, the amount of sludge will probably be about 38 tons a day.

The treatment works in the district are so placed that the sludge can be transported by water or rail. It would be possible, therefore, to dispose of it either at sea or on land. The presence of two garbage incinerators, both almost directly on railroad lines, would make it feasible to burn the sludge and garbage together. Centrifugal dryers might be placed at each disposal plant to dry the
20 sludge before transportation, or it might be more economical to install such dryers at one or both incinerators and transport the larger volume of wet sludge to the incinerators in proper cars.

There is a large amount of waste land along the railroad line in the northwestern part of the island, near Arthur Kill, which would be suitable for filling with the dried sludge from the settling tanks,

If the sludge were transported hither without previous drying, it would probably be necessary to establish drying beds near the railroad before the sludge could be made available for filling purposes.

If the sludge is to be disposed of at sea, it would be advisable to collect it at one or two points, to avoid construction of piers and loss of time in the operation of sludge steamers. For the purposes of this report, it has been assumed that all the sludge would be delivered wet into tanks located at the Stapleton treatment works, from which tanks a sludge discharge pipe would run out on the municipal pier. By this plan no new piers would have to be built and the sludge steamers passing out of the harbor from other treatment works would have to deviate only slightly from their course to serve as carriers for the Staten Island sludge.

Cost of Main Drainage Works.

The estimated costs of the main drainage works proposed in this report, not being based on detail designs, are necessarily of a preliminary nature.

The following tables give a concise summary of the estimated cost of construction and of the annual charges for maintenance and operation. The costs of land and rights of way are not included.

Estimated Cost of Construction.

Sub-division.	Sewers.	Pumping stations.	Outfall pipes.	Grit chambers.	Treatment works.	Total without Engin'g, etc.	Engineering & contingencies, 15%.	Total Costs.
Quarantine	$38,225*	8,000	6,000	.....	8,000‡	60,225	9,035	69,260
Stapleton	62,430†	10,000	3,000	3,500	63,000	141,930	21,290	163,220

3 *Study of the Collection and Disposal of the Sewage of the Lower Hudson, Lower East River, and Bay Division.*

Honorable William J. Gaynor, Mayor of the City of New York:

SIR: This report, the sixth in this commission's series of Preliminary Reports on the Disposal of New York's Sewage, is issued with the object of making public, at the earliest practicable date, this commission's studies as to the way in which it will be necessary to deal with the sewage of the fourth, and last of those divisions into which New York has been divided to facilitate the work.

While many details still remain to be considered, these studies show the general character of the works which should be constructed. To protect the Harlem and Lower East Rivers, large sewers are needed to intercept the sewage and carry it to an artificial island to be built near the outer limits of the harbor about three miles from shore; here, after a short and inoffensive treatment the sewage can be discharged into the ocean with confidence that the organic matters will be promptly rendered inert. All the rest of the sewage in this division should be passed through screens and grit chambers and discharged beneath the surface of the water in the main tidal channels.

1.—Boundaries and Topographical Features.

The territory in the Lower Hudson, Lower East River and Bay Division lies on both sides of the Lower East river, the west side of Manhattan and the east side of Upper New York bay. It extends from the extreme northwestern boundary of the city to below the Narrows.

It contains the largest population, and the most densely settled sections of any of the four divisions into which the commission has divided New York for the purpose of planning the main drainage and sewage disposal works which will be required. Within it lies the major part of the Boroughs of Manhattan and Brooklyn, which were separate cities until 1898.

This division is bounded on the east by a line which begins at Bensonhurst on Gravesend bay, runs in an irregular course northeasterly to Forest Park, in the Borough of Queens, and thence northwesterly to the East river near the mouth of the Harlem river. All of that part of Brooklyn and that part of Queens which lie to the west of this boundary line are included in the division.

4 Crossing the East river the boundary enters upon Manhattan Island at East Eighty-second Street, proceeds northwesterly to Central Park West, which it crosses at Ninety-first Street, and thence follows an irregular northerly direction along the height of land to the Harlem river at Spuyten Duyvil. That part of Manhattan, which lies to the south and west of the boundary so described, lies in this division. A small part of the division borders on the Hudson between Spuyten Duyvil and Yonkers. The west-

ern boundary of the division is formed by the Hudson river, Upper New York Bay, the Narrows and a part of Grave-end bay.

In the northern and southern parts of this division the topography is favorable to drainage, but there are large areas near the center which are so low and flat that the construction of sewers with sufficient grades to insure self-cleansing velocities and outfalls so situated as to provide for a free discharge at all stages of tide is impossible.

Made Land.—Many of the sewers in Manhattan feel the effect of the rising and falling tide for a considerable distance from the shores, in some instances, for over one mile. The worst cases of this kind are usually ascribable to the inadequate filling of low-lying or submerged areas as the beds of creeks and the once marshy shores of water courses. A remarkable regular shore line, made by filling in Manhattan, is shown on modern maps.

TABLE I.

Acres of Filled Land in this Division.

Borough.	Acres.
Manhattan	1,140
Brooklyn	1,520
Queens	460
Total	3,120

The filling has been largely, but not entirely, done along the water front. From 82nd Street on the Hudson river, southward, to the Battery, and thence northward along the Lower East river to 33rd Street, Manhattan, the marginal street is entirely on made land, the total length of shore so recovered being ten and one-half miles.

In many instances the made land extends some blocks back
5 from the river front and in the neighborhood of Canal Street, Manhattan, it runs across the island, a distance of nearly two miles.

On the Brooklyn shore, the made land extends from a point north of Newtown creek to near 45th Street, South Brooklyn, a distance of eight miles. The Brooklyn Navy Yard is entirely on made land. A large area in the neighborhood of Red Hook and Gowanus canal, Brooklyn, has been reclaimed by filling.

The growth of made land has been gradual. It has increased with the increasing size of the city. The chief object in filling in the low-lying places has been to eliminate swamps and marshes and make the area of ground available for trade and commerce more extensive than originally existed. At the same time the filling has proved a convenient means of disposing of refuse.

If cellar earth and other suitable refuse material were utilized in filling in the swamps and meadow lands which exist in the outlying parts of New York City, the shore lines in parts of the harbor estu-

aries which are now seriously polluted would soon be straightened and the water would be more easily kept clean than under the existing circumstances.

To facilitate the filling in of the low-lying shores, the Harbor Line Board, composed of engineer officers of the U. S. Army, which has charge of maintaining the navigable channels of the harbor, has established lines for solid filling. These lines extend throughout the harbor and give a good idea of the plans to which future operations of filling will probably conform.

The land which lies in this division at elevations within twenty feet of mean sea level, includes all the filled land and also some additional areas mostly in Brooklyn and Long Island City. A broad belt runs from the head of Newtown creek to the vicinity of the Brooklyn Navy Yard. The total area below twenty feet elevation in this division is about 3.3 square miles in Manhattan; 6.5 square miles in Brooklyn and 2.9 square miles in Long Island City. Seventy-three per cent. of all the land in this division is of more than twenty feet elevation above mean tide. In Manhattan the high land lies for the most part near the center of the island. The highest point is somewhat above 100 feet, and is situated north of 77th Street. There is no point above sixty feet elevation further south than 33rd Street.

In Brooklyn the land, which lies at an elevation above sixty feet, exists chiefly in the eastern part of the division, where a well recognized ridge runs in a northeasterly direction from the vicinity of the Narrows. Elevations of 100 feet or more frequently occur on this ridge.

6 Tidal Range.—The difference between mean sea level and mean high water is one-half the mean tidal range as given in the Table II.

TABLE II.

Range of Tide in New York Harbor.

	Mean.	Spring.
Lower bay, Sandy Hook	4.7	5.6
Narrows, Fort Hamilton	4.6	5.6
Upper bay, Governor's Island	4.4	5.3
Hudson river, Spuyten Duyvil	4.0	4.8
East river, Hallett's Point (Hell Gate)	5.5	6.6
East river, Throg's Neck	7.2	8.5
Harlem river, High Bridge	6.0	7.2
Kill van Kull, Shooter's Island	4.6	5.5
Newark bay, Passaic Light	4.7	5.7
Passaic river, Newark	5.0	6.0

Geology.—The superficial geological formation of this division is recent except for a small low-lying area of stratified drift in and near 125th Street. The surface of Manhattan island as far south as

23rd Street is composed chiefly of mica schist rock. South of 23rd Street, the rock disappears and stratified drift predominates.

In the Brooklyn part of this division, drift exists on each side of the central ridge, the ridge itself exhibiting the features of a terminal moraine with till on the western slope. Swamp and marsh lands exist to a limited extent, and then only in that part of Queens which lies in this division.

Value of Land.—The most valuable land in this division lies in the central and southern parts of Manhattan. It is a peculiar fact that whether for business or residence purpose, the most costly land lies along the center of the island. At the southern extremity is the financial district. North of this is the City Hall with the central post-office, numerous newspaper offices, the principal law courts and municipal administrative headquarters. Next above follows the wholesale dry goods center, then the region of retail shops, hotels and theatres and finally areas of high-class private residences and apartment houses which extend to the northern limits of this division. From this central zone east and west to the river front lie areas occupied by factories and residences, the latter ranging from modest dwellings to congested tenements.

In Brooklyn the water front is chiefly occupied by large factories and warehouses. The most crowded residence district and the center of financial administrative activity lies in that part of the borough which is opposite the southern end of Manhattan Island.

7 2.—The Existing Sewers—Their Outfalls and Resulting Nuisances.

Practically the whole of this division is sewered on the combined principle of sewerage.

In addition to the sewage which comes from the storm water of the streets and from the interior of the houses, the sewers of Manhattan and Brooklyn are required to carry away the water which falls upon the roofs, yards and courts of the buildings. The connections are trapped in order that the air from the sewers shall not enter the houses. The plumbing of the houses is ventilated by extending the soil pipes to the roofs.

In many cases, especially in Manhattan where the cellars of large buildings are deep, it is often necessary to pump the sewage into the street sewers. This is done at private expense.

Relief Sewers.—In most of Manhattan the sewers, which are large and short, have generally proved adequate to the requirements of the growing population; but in Brooklyn much trouble has been experienced from the insufficient provisions which were early made for drainage. The first sewers were built when the populations which they were required to serve were small and scattered, and when a comprehensive system of sewers was built betwen 1850 and 1860, the rainfall data were inadequate to permit designers fully to understand the requirements. With the increasing population the original sewers have been supplemented by large and expensive relief sewers, and these in turn have had to be assisted in some cases by the con-

struction of intercepting sewers for the collection and removal of storm water.

The sewers of Manhattan and Brooklyn are of many shapes and sizes. Among the older sewers of Brooklyn are many storm drains whose courses are not known. The older sewers are generally circular in shape, and when over twenty-four inches in diameter are of brick or concrete. Clay and cement pipe have been extensively used for the smaller sizes. Since 1907 the principles of design and construction have been much improved in Brooklyn.

Most of the sewer outlets on the Manhattan shores are between two and five feet in diameter, but there are some which have a section equivalent to a circle having a diameter of ten feet and more. The outlets on the Brooklyn shore are somewhat less numerous and some are larger than the largest of Manhattan, having a section equal to a circle with a diameter of fifteen feet.

Many of the sewers of Manhattan were built many years ago. They represent various periods of growth due to the introduction of public water supplies and other causes and have been extensively reconstructed and repaired within recent years.

8

Throughout this division the sewers are provided with catch basins at the street corners which were intended to convey the storm water from the gutters and protect the sewers from grit and other solid substances.

Ventilation.—It was intended that the sewers throughout this division should be ventilated through perforations in the manhole covers located at frequent intervals in the street. In most parts, notably in the older sections near the water front, the ventilation is defective, partly as a result of the settlement of the sewers, the entrance of tide water and the submergence of the outlets. Nuisances frequently result where steam and hot water are discharged into the sewers, since hot vapors rise and issue through the manhole covers disseminating odors of cooked sewage.

Outlets.—The outfalls of the sewers of this division, as elsewhere in the metropolitan district, are located at the bulkhead or shore line or, frequently in Manhattan, near the outer ends of the docks and piers.

The submergence of the sewer outfalls, as at present, and the rising of the tide drive the foul air into the streets and produce coatings of grease and solids upon the sides of the sewers, and this interferes with the flow of sewage. So much deposit is produced in some of the sewers that a cleaning gang, working continuously, can make no appreciable reduction in the depth of the deposit. Congealed grease has been found to measure as much as a foot in thickness in some of the sewers of Manhattan.

Physical Condition.—Inspections of the sewers made by the Metropolitan Sewerage Commission with the co-operation of the Bureau of Sewers and the Borough President of Manhattan have revealed many examples of distorted shapes, worn out inverts, sunken arches, and cracks due to settlement. In many places irregular holes had been broken through sewers in making connections, and the holes never properly repaired. It was impossible to enter some of the

sewers for inspection owing to steam and hot water escaping from neighboring buildings. Other sewers could not be entered on account of the presence of illuminating gas in such quantities as to endanger health. In other areas, lanterns could not be carried into the sewers on account of gasoline vapor, presumably from automobile garages or other establishments using this explosive compound.

In Manhattan the sewers are inspected and cleaned only on complaint. The sewers are not flushed, but are cleaned by hand. Street sweepings are frequently pushed into the catch basins against orders in Manhattan and Brooklyn.

9 Catch Basins.—The effect of the catch basins is comparatively slight. They soon become filled with grit and other solid matters. To be of material use, they should be cleaned after nearly every storm. This is not done. The records for the year 1909 show an average of one cleaning for each catch basin in Manhattan every 5.3 months. This does not mean that all the 6,348 catch basins in the borough were cleaned. Some were cleaned out at compartively frequent intervals and others were not cleaned at all.

In the year 1907 the catch basins in Brooklyn were cleaned on an average about 2½ times a year and the quantity of deposits removed aggregated 35,272 cu. yds. The cost of removing this material was $1.12 per cubic yard. The incompleteness and great cost of removing solid matter from sewage by the use of catch basins can be readily understood from these figures.

Large quantities of solid matters which pass the catch basins are deposited in the sewers themselves and are eventually removed by hand, washed out by the flood water of storms, or carried away through the alternate choking and flushing action which is produced by the rising and falling tide.

About 400,000 cubic yards of deposits are dredged each year from the slips and docks of that part of Manhattan which lies in this division by the Department of Docks and Ferries and large quantities are also dredged by private enterprise and from the Brooklyn shores. It is generally conceded that this solid material comes chiefly from the sewage. The water from which the deposits are taken is often black and offensive and gases of putrefaction rise in innumerable bubbles from the deposits at the bottom. During flood currents the sewage matters are driven back into the slips and in this quiet water some of the solid matters are deposited. On the outgoing tide grease and excreta are left adhering to the dock walls and piers. In the immediate vicinity of the outfalls the water is discolored and objectionable in appearance and odor. In some cases many acres are rendered turbid by the sewage.

Local Nuisances.—Extensive nuisances occur in this division at various points along the Brooklyn shores. Gowanus canal, Wallabout bay and Newtown creek are the most conspicuous. These bodies of water are actually large, although small in comparison with the great areas of the main divisions of the harbor. The condition of Gowanus canal, into which a 15-foot relief sewer as well as some eight other sewers ranging from 1½ to 6½ feet in diameter discharge, has been notorious for years. The water is black and

foul-smelling at all times and the sides of the piers, bulkheads and masonary structures are coated with deposits. As a means of improving this canal, the Borough of Brooklyn has constructed
10 a flushing tunnel which leads from the head of the canal to an outlet in the Upper bay. Pumps force the water from the head of the canal through the tunnel, which is 6,270 feet long and 12 feet in diameter. The outlet is about 2 feet below low tide and is situated close to the shore between two long piers. The water in the vicinity of the outlet is strongly discolored when the pumps are in operation, the discharge from the tunnel being visible at times for a distance of more than a mile.

Wallabout bay in the Lower East river is polluted by a 9-foot sewer which discharges at the bulkhead line. The point of discharge is so protected from the tidal currents that a satisfactory dispersion of the sewage cannot take place. The bay is exceedingly offensive at all stages of tide, the bottom being covered with putrefying sewage sludge and the top with sewage apparently in an undiluted state. These objectionable conditions are in front of the New York Navy Yard.

Newtown creek, which empties into the Lower East river from a low-lying manufacturing district north of Brooklyn, is an offensive body of water. It supports a heavy traffic. Considerable quantities of manufacturing wastes are discharged into the creek from warehouses, elevators and factories, which line both banks. Some sewage empties into it, although the further pollution of this stream is prohibited by law. A 15-foot sewer, constructed through the joint action of the Boroughs of Brooklyn and Queens, empties into the head of Newtown creek and although this sewer was intended to accommodate storm water only, the dry weather flow being diverted, considerable pollution is ascribable to it.

There are no figures available to show the total cost of the sewers which exist in this division. It has been estimated that those of Manhattan exceeded $26,000,000, and it is believed that those of Brooklyn have cost about an equal sum. There are about 522 miles of sewers in Manhattan and about 814 miles of sewers in Brooklyn.

3.—Possibility That the Sewers of Manhattan Will Have To Be Rebuilt.

It has seemed to those charged with the duty of maintaining the sewers of Manhattan, as well as to consulting engineers who have been called upon to examine into the subject, that it would eventually be necessary to reconstruct a large part of the existing sewers of Manhattan.

The chief reason for reconstruction lies in the need of repairs and the harm done to the sewers from the building of underground structures of various kinds, as, for example, passenger subways, conduits for electric light, telephone and telegraph and pipes
11 for water, gas, steam and pneumatic mail service. As the city is entering upon extensive subway construction, it may be well to consider whether the interferences which now exist or are to be expected will not cause so much expense and make the

sanitary removal of the sewage so difficult that a reconstruction of the sewers will be a practical necessity. If the sewers are to be rebuilt, this fact should be known and preparations for it made at once so that such saving as can be effected in the cost of temporary alternations can be accomplished.

Right of Way of Sewers.—Of all the many structures beneath the city's streets, it is most important that the sewers should have the right of way. Unlike pipes for water, gas or electricity, which operate under pressure, sewers, whose flow is due alone to gravity must be laid to proper grade and alignment or they will not operate properly.

To be self-cleansing, sewers should maintain a certain velocity of flow and any reduction in the grade which checks the velocity will lead to deposits. Short turns and bends and changes in the cross section also alter the flow and interfere with the proper function of the sewer.

When it is remembered that sewerage systems should be well designed and constructed; that they are built under the ground in a manner which is intended to be permanent and durable; that they cannot be altered in size, shape, grade or location without harmful consequences; that their function is to carry off promptly and completely the most offensive and dangerous wastes of a city, the claim of the sewerage system for right of way beneath the streets appears to be fully justified. That this claim has not been respected is a regrettable fact. In defiance of the officials charged with the duty of maintaining the sewers, they have been moved from place to place, pierced and damaged in many ways. Instead of being used for the purposes for which they were built, the sewers have been abused by the discharge into them of harmful manufacturing wastes, hot water and steam and been rendered dangerous for inspection by the illegal emptying of gasoline and other inflammable compounds.

The structures which interfere with the sewers are located at depths which range from that of the shallow conduits which carry the current for the surface railways to that of the passenger subways. The passenger subways form a serious obstruction. They are situated as close to the surface of the street as practicable in order to facilitate entrance and exit and they require over 20 feet of depth. For the most part the subways, like the water, gas and other large mains run longtitudinally through the island and the sewers in seeking their outlets to the rivers run perpendicularly to them.

12 Interference from Subways.—The first subway for passengers was built on a line which divided the sewerage systems of Manhattan into approximately two equal groups, the subway following along the axis of the island for most of its length. The interference with the sewers was, in this case, as slight as possible, it being feasible to cause the sewage to flow in many instances with but little alteration of the sewers to a convenient point of discharge to one of the nearby rivers on the east or west side of the island. But other subways which had been designed will run in lines nearly parallel to the first and will divide the sewers further. There will be no easy readjustment possible, as in the first case, for there will

be a central area which will be blocked off by the subways from the river on either side. In order to carry the sewage past these new subways, it will be necessary to make extensive reconstructions. It will be necessary to collect the sewage to more or less suitable points in the areas between the subway lines and then conduct it by siphons beneath the subway structure to points from which it can flow away by gravity. The alignment and grade of the sewers will, in many cases, be seriously interfered with. The siphons which should be capable of being emptied, inspected, repaired and cleaned, will be costly to build and, when of considerable depth, difficult to maintain. Sewage which now flows directly across the island will have to be diverted so as to run for considerable distances longitudinally, with the result that there will be a tendency to loss of velocity and formation of deposits in the drains.

Need of Repairs.—An important argument for reconstructing the sewers of Manhattan lies in the need for repairs. Inspections made by the Metropolitan Sewerage Commission have shown that some of the sewers, and especially the older ones, are in dangerous condition. Of 246 inspections, 38, or one-sixth, showed places where the sewers will have to be rebuilt within a few years on account of defective brick work alone. These locations exist along the whole length of the island. Of the 522 miles of existing sewers in Manhattan, 55 miles are seriously out of repair. To repair these, would involve an outlay which could more profitably be spent on new construction.

Separate vs. Combined System.—If the sewers were reconstructed, it is the opinion of many engineers that they should be built upon the separate system. Drains for storm water should be laid close to the surface of the streets and should be large and have ample grades to carry off much solid matter. When street washing, which is rapidly coming into favor, becomes general in the city, the quantity of grit and other solids to be removed by the sewers will increase. To a great extent the storm sewers should be made to carry off snow. Storm sewers should be built without catch basins at the street corners and should lead to central points where grit and
13 other heavy materials can be removed before the sewage is discharged into the harbor. The elimination of the 14,000 catch basins which now exist would be desirable.

Sewers for house drainage should be laid so far beneath the surface of the streets as to permit the sewage to flow into them by gravity. They should be sufficiently deep to pass clear of all other subterranean structures. The comparatively small size which the sewers for house sewage would require would permit them to be located, even in congested streets, so as to give good alignment and grade. The sewage would thus be more promptly carried away than under present circumstances. In general these sewers would run perpendicular to the subways, crossing under them and delivering at suitable places into interceptors for conveyance to sewage disposal works or pumping stations.

Objections Against Reconstruction.—The objections to the reconstruction of the sewers of Manhattan lie in the expense and incon-

venience which the reconstruction would directly and indirectly entail upon the public. Almost all the streets of the city would require to be opened and the large quantities of earth and materials of construction would have to be handled without stopping vehicular traffic where the alterations were going on. The plumbing of over 150,000 houses would require to be altered so that the proper sewer connections could be made.

It is not clear how the storm water sewers, which should be laid close beneath the surface of the streets could escape the underground trolley conduits above, and the passenger subways beneath, in the longitudinal highways. There should be no siphons on these storm water drains.

Storm Water.—If the house sewage and storm water were collected separately, the disposal of the sewage would be facilitated, provided the storm water was not treated also.

It is not customary for cities to build works to treat all their storm water. The volume is so great, even when moderate falls of rain occur, that the works required to purify all the storm water would be excessively large and costly. There is, moreover, a general belief that the waste water from the roofs of houses and from the streets does not contain enough putrescible material to add materially to the pollution.

The literature relating to the treatment of storm water shows that experts generally consider that storm water from closely built-up cities is capable of producing at least as much offense as house sewage. There is reason for believing that the first flush of storm water is worse than even the relatively concentrated sewage of European cities, and that it is therefore desirable to treat a portion of the storm water.

14 European and American Sewage.—Much of the recorded information and opinion which exist with respect to the polluting effects of storm water is based upon European conditions, where the quantity of sewage at times of dry weather may amount to 20 or 30 gallons per capita per 24 hours. If the quantity of sewage in American cities is taken at 120 to 180 gallons per capita, it is evident that the argument for treating storm water has more weight in America than it has abroad, for if storm water is as bad as domestic sewage when the latter is concentrated to the extent of 20 or 30 gallons per capita per day, it must be about six times as bad when the domestic sewage is so dilute.

The aggregate weight of solid matter carried by storm water is very great. Analyses can be quoted which show that the percentage of suspended matter is several times as high in sewage containing storm water as it is in purely house sewage. This being so, and it being remembered that the volume of sewage is greatly increased at times of storm, it follows that the total amount of suspended matter carried by a given volume of storm water is much greater than the analyses indicate.

Numerous experts have expressed the opinion that careful attention should be given to the polluted character of the first flush of storm sewage. In the opinion of Samuel Rideal, whose familiarity

with the chemical and biological composition of sewage and whose knowledge of current practice in England entitles him to be regarded as an authority, "whatever system be adopted, the raw storm water of populous districts should never be allowed to pass in large volumes at the beginning of a storm directly into a stream." Dr. Dunlap, Director of the Hygienic Institute at Hamburg, and an authority on sewage disposal on the Continent of Europe, as well as in England, says: "It must not be supposed that the contents of rain water sewers are in general not so polluted as ordinary sewage. In busy districts, the washings from the streets, even if these are thoroughly cleaned daily, are everywhere found to be worse in every respect, including putrescibility, than ordinary sewage. Dr. Houston, the celebrated English bacteriologist, says that storm water is as "potentially dangerous to health as normal crude sewage." To these opinions many more could be added to the same effect.

American Analyses.—There is scant information on record to show the composition of storm water in American cities, although some data are available to indicate the average composition of sewage containing the combined drainage of houses and streets. This information is not as valuable as it would be if it had been collected with the intention of showing the difference in composition which occurs in the sewage of a given city during dry weather and at periods of storm, but some facts exist with respect to this subject.

15 At a testing station, established at Gloversville, N. Y., at which analyses were made continuously for about one year, 1908-1909, the marked effect of storm water upon the dry-weather flow was shown in the following manner. Following a period of dry weather, rain fell for practically 24 hours on June 5 and the flow of sewage increased 31 per cent., although comparatively few storm-water drains were connected with the sewers. The storm water came chiefly from the roofs of houses and from the streets. The strength of the sewage increased as follows:*

Total suspended solids from 312 to 622 parts per million, or 166 per cent.

Volatile suspended matter from 196 to 254 parts per million, or 73 per cent.

Fixed suspended solids from 116 to 368 parts per million, or 324 per cent.

It is worth noting that the largest increase in suspended matter was due to non-volatile, fixed or mineral matter. This suggests that storm water is peculiarly susceptible of improvement by settlement, an inference which is not strictly correct, for the removal of mineral matter would not produce nearly as much benefit as the removal of organic or nitrogenous matter. A large part of the suspended matter is grit.

The average composition of the combined sewage of some American cities, as determined by numerous analyses made at investigating laboratories, is indicated in Table III.

* Report to the City of Gloversville, N. Y., by Eddy and Vrooman, Aug. 7, 1909, p. 57.

16 In each of the investigations whose results are indicated in the foregoing table, an effort was made to obtain results which would be helpful in the design of works for the purification of the sewage. Certain peculiarities were thought to exist in the sewage to be dealt with which it was necessary to determine and the amenability of the sewage to purification was tested in each case.

It will be observed that the sewages tested at the experiment stations varied considerably in the amount and nature of the suspended matter, as well as in the dissolved impurities. If partial treatment only had been thought sufficient, it would not have been necessary to make the analyses so complete. So far as the general character of the average sewage dealt with is concerned, the figures given are satisfactory, but they should be employed with caution in forming an opinion as to the composition of the sewage of other cities where importance attaches to questions of detail.

Opinion With Respect to Manhattan and Brooklyn.—Should the house and storm sewage of Manhattan be collected in separate systems, it would be desirable certainly to treat all of the one and perhaps part of the other. This could not conveniently be done in the same plants. Should both house and storm sewage be collected by the combined system, the treatment works should be so designed as to deal with the dry-weather flow and have enough more capacity to take care of the heavily polluted water which would be washed from the streets and houses with the first flush of the rain. It would be well to have the capacity of the main sewers and disposal works equal to twice the average dry-weather flow.

4.—Quantity and Composition of the Sewage.

The quantity of the sewage produced in this division can be estimated from a knowledge of the water consumed and the rainfall. But few of the sewers have been gauged and exact measurements of their flow are not available. As compared with many cities, especially those of Europe, the volume of sewage is large and its composition variable. It is, for the most part, remarkably fresh when discharged, owing to the short distance, and consequently brief time, consumed in passing from the houses to the outfalls.

The conditions of residence and manufacture are various in this division and the sewage which reaches the outfalls is correspondingly variable. The quantity produced is different at different hours of the day and night; and it is not the same at all seasons of year. Owing to the fact that most of the sewers for some distance from the shores of the harbor are choked with tidal water, the sewage is often mixed with salt water before it is discharged. In some cases
17 the sewage is warm with the waste water and hot water which is discharged from large office buildings, hotels and manufacturing establishments.

At times of rain much polluting water is washed from the streets. The quantity of this material is doubtless increasing, due to the more extended practice of washing the streets with water. After snow storms, snow is, to some extent, discharged into the sewers and with

it more or less solid matter, which was either present on the pavements before the beginning of the storm or is thrown out after the snow begins to fall.

In the report of the Metropolitan Sewerage Commission, dated August, 1912, pp. 28-30, is given an estimate of the composition of the sewage and the quantities produced in various parts of the metropolitan district. The composition is based on an ideal sewage whose constituents are stated. It is shown that about 625 tons of fecal matter is discharged into the harbor every day. Assuming the population in the year 1910 to have been 6,423,635 for metropolitan New York and New Jersey, and supposing that 90 per cent. of this number were connected with the sewers, the total number of persons contributing to the pollution of the waters would have been 5,780,000. The aggregate quantity of polluting matter estimated as dry solid material which was discharged in the year 1910 would have been 266,000 tons. About one-half of this was capable of putrefaction or already advanced to some extent toward that condition when discharged.

Assuming one ton of dry suspended matter to be equivalent to about 45 tons or about 53 cubic yards of wet sludge, it appears that the population of the metropolitan district empties into the harbor each year the equivalent of 12,000,000 tons of sludge, having a bulk of about 14,000,000 cubic yards.

Data relative to the population and sewage flow in different parts of the metropolitan sewage district, including the waters of this division, are given in Tables IV and V.

The Tables.—The eight divisions into which New York harbor has been separated for purposes of study have been described in the commission's report of August, 1912. To these is here added a ninth to include the sewage which is naturally tributary to the Passaic and Hackensack rivers.

In preparing Table I, the dry weather flow of sewage discharged into each division has been assumed to be the same as the volume of the public water supplies of the areas tributary to the respective divisions. Where future quantities are considered, the sewage to be expected is in most cases based on the estimate of the authorities who are charged with the duty of providing the public water supplies.

The populations for 1910 have been taken from the United States census reports; those for 1940 are based on carefully made estimates by this commission, revised with the latest information obtainable.

Table IV.

Populations and Volumes of Sewage Directly Tributary to the Several Divisions of the Harbor.

Division of the Harbor	Sewage.	Year 1905. Sewage Mgd.[1]	Population	Gallons per capita per day.	Year 1940. Sewage Mgd.[1]	Population.	Gallons per capita per day.
Harlem River	Manhattan	70	522,000		156	900,000	
	Bronx	29	275,000		97	748,000

			Queens			81,000			290,000	
				70	351,000	151	163	960,000		180
Passaic and rivers	Hackensack	New Jersey		130	950,000	137	249	1,500,000		184
Totals				765	6,019,000	...	1,719	11,570,000		...

• Million gallons per 24 hours.

From Table IV it will be seen that the total quantity of house sewage tributary to the harbor in the year 1910 was 765,000,000 gallons per 24 hours, and the population supplying this sewage was 6,019,000. By 1940 the population will be almost doubled and the quantity of sewage will be more than doubled. The sewage expected in 1940 in one day will be enough to fill a reservoir one square mile in area and 10 feet deep.

19

A glance at Table IV shows that a proportionate burden of pollution is not placed upon each division. The Lower East river receives much more sewage than any other division in comparison with its size. This will be true, also, in 1940, if nothing is done to prevent it. At that time over one-fourth of the total amount of sewage produced in the metropolitan district will be directly tributary to this stream. The increase which will go to this division from Brooklyn and Queens will be about half the quantity which was produced by Manhattan in 1910.

Table V has been made from data contained in the report of this Commission dated August, 1912. Of particular interest are the suspended organic and volatile maters.

TABLE V.

Assumed Composition of the Sewage which is Tributary to the Harbor on the Basis of 100 Gallons per Capita per 24 Hours. The Quantities are Expressed in Parts by Weight per Million of Water.

Solid Matters	800	Nitrogenous	150
Dissolved	500	Nitrogen	15
Suspended	300	Non-Nitrogenous	250
Organic and Violatile Matters	400	Fats, etc.	50
Dissolved	200	Total Carbon	200
Suspended	200		

5.—Impossibility of Disposing of All the Sewage Through Dilution With the Harbor Water.

The discharge of sewage into a natural body of water is properly termed disposal through dilution. Dilution aids in the disappearance of the sewage, but it is only one of a number of factors which must come into play before the solid and liquid ingredients can permanently disappear.

Oxidation Essential.—For the disposal of sewage to be permanent, it is necessary that the decomposable ingredients shall be transformed into other and simpler chemical compounds. These transformations involve physical, chemical and bacteriological reactions. The final and indispensable change is really one of combustion; oxygen is absorbed and the substances which were offensive, or likely to become so; are mineralized. In this state and by this process alone do they become inert and incapable of producing offense.

It is the aim of all processes of sewage purification to oxi-
20 dize the decomposable ingredients or prepare them for oxida-
tion. In the land treatment of sewage, the ingredients are oxidized near the surface of the ground. In sprinkling filters and contact beds, oxidation is accomplished by bringing the sewage into intimate contact with the air on the surface of broken stones. The effect of dilution is to bring the liquid and solid particles of the sewage into contact with the oxygen which is dissolved in the water In all these processes the end is essentially the same. Oxidation is the object aimed at.

In treating sewage by disposal upon land, in filter beds or in water, the sewage should be freed from its gross suspended solids before it is subjected to the final oxidizing process and if this is properly done, there is likely to be little trouble so long as the quantity of oxygen is sufficient and time enough is afforded for the oxidizing process to become complete.

If the ratio of sewage to oxygen is too great, serious consequences follow and this is as true when sewage is discharged into water as when it is passed through filters or placed upon land. The evil effects include discoloration, the evolution of foul smelling gases and the production of slimy, semi-solid deposits. Land and filters in this condition are said to be sewage-sick and water is popularly called stagnant. The condition is one of putrefaction.

Putrefaction is decomposition in the absence of oxygen. It postpones, but cannot replace, oxidation. Oxidation must eventually take place and if it does not occur promptly and under conditions which are within control, it will occur under such conditions as may accidentally and ultimately offer.

The Supply of Oxygen.—The exact amount of oxygen which should be supplied to sewage in order that decomposition should proceed at the most rapid rate or, at least, at a reasonably rapid rate is probably not determinable. The action is essentially a biological and chemical process in which time and temperature are important factors. The organisms which carry it on must be provided with all the oxygen which they need. It is impossible for them to have too much.

Clean water generally holds a large amount of oxygen. One thousand volumes made up of half sea water and half land water, uncontaminated with sewage and without decomposing matters of any kind, should have at 65 degrees Fahrenheit, 6 volumes of oxygen per litre or about 8.6 parts per million by weight. The harbor water in this division usually contains from two-thirds to one-half of what it should possess. The oxygen that has disappeared is the measure of the organic pollution.

Dilution Required.—As a result of observation and experiment in various parts of the world, engineers have formed opinions as to the amount of sewage which can safely be discharged into a natural
body of water, such as an inland river or lake. The word
2? safely here refers solely to the chance of producing a nuisance, chiefly odor. It has no relation to the effect which the sewage may have upon health.

According to the opinion of American engineers, the dilution must be in the proportion of at least 20 or 25 parts of water to one part of ordinary sewage and there may be conditions where a nuisance may result where the dilution amounts to nearly 50 parts of water to one part of sewage. When the proportion of sewage to water is greater than this, the capacity of the water is likely to be overtaxed. These supposedly safe ratios of dilution are based upon the assumption that the water with which the sewage is mixed is clean and possesses its normal amount of oxygen. Where the water is polluted to begin with the necessary dilution must be much greater.

In the Eighth Report of the Royal Commission on Sewage Disposal of Great Britain, issued at the end of 1912, it is recommended that where the dilution of sewage to water is between 150 and 200 times, the sewage should be purified so that the effluent will not contain more than 60 parts of suspended matter per million and that only when the dilution exceeds 500 times the volume of sewage should crude sewage be permitted to be discharged into a water course. These figures refer to English sewage, which is about 6 times as concentrated as American sewage, and to the water of inland rivers and lakes, but the Royal Commission holds the opinion that the proportions hold generally true for tidal waters also.

A glance at Tables VIII, IX and X of this report will show that the sewage in this division was not diluted with a proper amount of water in 1910, and will be still less adequately diluted in 1940 if measures are not taken to reduce the pollution.

It is worthy of note that the observations upon which American and English experts base their opinions have been made where sewage has been discharged into inland bodies of water. There has been no study of the discharge of sewage into tidal estuaries which would permit of safe ratios to be stated with positiveness for salt water. Such investigations as have been made indicate that sewage solids settle more rapidly in salt water than in land water, and it is believed that gallon for gallon, land water will dispose, in a normal manner, of more sewage than sea water.

It is not always clear how the dilution of sewage can be calculated in sea water. The same, or nearly the same, water often flows backward and forward for days near a sewer outfall, while the discharge of sewage is continuous. Under these circumstances the sewage flow is irregular and its calculation is involved in uncertainty.

22 Errors which may be made in such calculations include the assumption that:

(*a*) The assumption that the flow of sewage is uniform during the 24 hours. It may vary as much as 50 per cent. at different hours.

(*b*) The flow of tidal water is uniform. It is quite the reverse. Aside from the fact that the currents at each turn must gradually slow down to the stopping point and then gradually increase to the normal strength of flow, winds, heavy rain, snow and intense cold may each produce a decided effect upon the volume of water moving in a harbor.

(*c*) The sewage matters become immediately and thoroughly mixed with the waters. The opposite is the fact. Dispersion and

diffusion are difficult to accomplish and consequently there are many kinds and degrees of stagnation.

(*d*) The sewage remains sewage after it is well mingled with the water. This is not true. Chemical changes at once set in.

(*e*) The waters into which the sewage is discharged are free from pollution to begin with. This assumption, however warranted in dealing with an inland river, is quite contrary to the fact as related to New York harbor.

The changes which sewage undergoes when it is discharged into a natural body of water should be carefully kept in mind, and the mistake, often made, of assuming that the sewage remains and can be reckoned with as sewage after admixture should be avoided. In no other way is it possible to obtain an accurate understanding of the subject. It is wrong to speak of sewage matters as sewage two or three hours after they have been discharged into a tidal estuary. Some of the original ingredients may still exist, but the chances are all against the continuance of any of them in an unaltered condition except the grosser solids and such others as may be able to persist in greatly diluted form.

Oxygen Required. It is impossible to say with any useful degree of accuracy how many pounds of oxygen one million gallons of sewage will require in order that the putrefiable ingredients may be rendered inert. The two ways of approaching this subject, that is, by analysis and incubation tests, are, unfortunately, too artificial to show what can reasonably be expected in nature. Predictions as to the amount of oxygen which would be present if a given quantity of sewage was to be discharged into a given quantity of water must, in the present state of knowledge, be considered unreliable.

But if it is impossible to calculate the oxygen requirements of sewage or express in percentages the proportions of sewage to water which may be present throughout a harbor, it is feasible to state, in at least approximate terms, the relation which exists between the volume of sewage and the volume of water present under various circumstances and such calculations may be of some value. They are likely to prove of greatest service when they are expressed in a simple way and are used with other data as a means of obtaining a general opinion of the case.

23

It was in this way, and with all the restrictions and qualifications which a knowledge of the situation imposed, that Prof. Adeney, in a report to the Metropolitan Sewerage Commission, calculated the dilution of sewage in New York harbor (See p. 95, Report Metropolitan Sewerage Commission, August, 1912).

Calculations of Dilution.—Taking his data from the published reports of the commission, Prof. Adeney calculated that about 59,400,000 cu. ft. of sewage flowed into the whole harbor during a tidal cycle of 12 lunar hours. Inasmuch as about 23 per cent of the water of the harbor flowed out on the ebb tide, the same percentage of the contribution of sewage would flow to sea at the same time, leaving about 77 per cent, mixed with the harbor waters at mean low tide. The quantity of liquid sewage matter subsequently remaining within the harbor would increase with each succeeding tidal

cycle until the quantity which passed out with the ebb tide became equal to that which drained into the harbor during the tidal cycle. This would occur when the total volume of liquid sewage, remaining intermixed with the harbor waters at mean low tide had become equal to about 195,500,000 cu. ft., which it would do after about 20 tidal cycles. The volume of liquid sewage matters passing out of the harbor through the Narrows would then continue to equal the volume of liquid sewage matters flowing into the harbor during a complete tidal cycle. That is, if 59,490,000 cu. ft. of sewage passed out of the harbor with each 12,310,000,000 cu. ft. of ebbing tide, the dilution of sewage to water would be in the proportion of 1 to 200 and the dilution to the liquid sewage matters remaining in the harbor at mean low tide would be in like proportion.

Both at the beginning and end of his calculation, Prof. Adeney took pains to fully explain that this calculation did not, as no calculation could, truly represent the facts.

In a report by Messrs. Black and Phelps, made to the Board of Estimate and Apportionment of New York in 1909, the question of dilution is dealt with at length, for it was believed to have an important bearing on the question of dissolved oxygen, and the authors considered that the oxygen should not fall below 70 per cent. of the amount which would be present if the water was saturated with it.

24 The sources of the water in each principal part of the harbor were assumed in accordance with volumes and velocities stated by the Coast and Geodetic Survey in 1886, and the proportion of water from each source was apportioned by the authors as, in their judgment, seemed correct. For convenience—these volumes were reduced to percentages of the whole and each was given a characteristic letter to facilitate computation. A series of equations was derived and the composition of the water of each part of the harbor was calculated for various tidal periods.

These studies were taken by the authors to indicate that the volume of pure sea water which entered the harbor between the Narrows and Throgs Neck every 12 hours was 29.135 million gallons and that this contained under summer conditions 1,946,218 pounds of dissolved oxygen. It was considered that if this oxygen were to be reduced by sewage to 70 per cent. of saturation, 583,865 pounds would be lost in 12 hours. The total volume of water in the harbor within the limits named was taken to be 251,418 million gallons, and it was stated that if this were reduced to 70 per cent. of saturation, it would absorb in 12 hours from the atmosphere 0.95 per cent. of its saturation value of 159,550 pounds.

The oxygen absorbed from the atmosphere plus the oxygen from the pure sea water would give a total of 743,415 pounds of oxygen. Finally, assuming that the sewage would be produced at the rate of 100 gallons per capita per day, the authors arrived at the opinion that the natural supply of oxygen would be sufficient to care for the sewage of a population of 7.4 millions, provided the sewage was discharged at the two ocean entrances.

6.—Ratios of Sewage to Water.

Some calculations of the ratios of sewage to water have been made by the Metropolitan Sewerage Commission which deal with comparatively small parts of the harbor and are consequently not greatly affected by the errors which are generally inseparable from such computations. But all calculations of this kind should be regarded as crude approximations of the truth.

There are three divisions of the water with which it is of interest to compare the sewage. First, the volume of water which is contained in the vicinity of an outlet at mean low tide; second, the volume of the tidal prism or quantity of water in the vicinity between the levels of low and high tide; third, the net ebb flow past the point where the sewage is emptied.

The Metropolitan Sewerage Commission has divided New York harbor into ten sections and the quantities of sewage which were discharged directly into these sections in 1910 have been estimated; the quantities of water in each section below mean low tide, in the tidal prism, and the net ebb flow through the section have been computed and the ratio between the sewage and the water has been calculated. Calculations based on estimates of future quantities of sewage have also been made.

In addition to these computations, estimates have been made of the aggregate weight of sewage impurities which are tributary to each section. These calculations are based on a definite composition of the sewage which is assumed and taken to be uniform for the whole territory. The composition assumed is that of the standard sewage as shown in Table V. The volume of the sewage for the year 1910 is based upon the public water supply. The volume expected in future is also founded upon anticipations of the drinking water requirements. The per capita volume of sewage being stated, it will be possible at any time to correct the estimates of weight of impurities discharged into the harbor in case either the composition or volume of the sewage becomes known. It is improbable that such knowledge can be obtained until main drainage works are built.

It has seemed desirable to calculate the quantities of sewage material which would be discharged into the various sections of the harbor in case the sewage was first passed through works for the more or less complete removal of the impurities. The processes of treatment which have been thought most worthy of consideration in this connection are such as have been well established by experience. Screens are considered because of their compactness and ability to operate with varying quantities of sewage and small head. Settling basins have been included because of their almost universal employment in sewage purification works and their efficiency in removing suspended matter. Chemical precipitation has been considered because it is one of the most efficient means for removing both suspended and dissolved matter at one process. Sprinkling filters have been included, since they represent the most effective means of oxidizing the sewage impurities in a given area of land.

It would be feasible, and it is customary where a high degree of purification is required, to combine two or more of these processes in a given plant.

The least effective process which seems worth considering for the sewage which is to be discharged into the harbor is screening, and the highest degree of purification practicable in most cases in the territory where the sewage is produced in screening and rapid settlement. More purification than this would require a greater amount of land than is procurable except at great cost and involve probable nuisance from odors and flies.

Estimates of the quantities of sewage discharged into New York harbor show that all sections do not receive an equal share
26 of pollution; the analyses of the water show that the circulation of the tide is insufficient to distribute satisfactorily the excessive burden which some sections receive. Some parts of the harbor are much more polluted than others, the region of greatest pollution being close to the most densely settled part of New York City. The Lower East river and Harlem receive large quantities of sewage from both shores.

Table VI.

Volumes of Water at Low Tide, in the Tidal Prism and the Net Discharge from the Several Divisions of the Harbor. The Quantities are Expressed at Million Cubic Feet.

Division of the harbor	Volume of water below mean low tide.	Tidal prism.	Net ebb flow in 12 lunar hours.
Harlem river	285	148	15
Hudson river, Battery to Mt. St. Vincent	12,330	1,697	1,087
Upper East river	5,512	1,869	.....
Lower East river	4,174	552	100
Upper bay	12,970	2,541	1,283
Newark bay	1,542	1,071	105
Kill van Kull	728	150	88
Jamaica bay	2,029	1,977	.....
	40,971	10,033	.....

Table VI was prepared partly from tidal data computed by this commission and partly from information supplied by the United States Coast and Geodetic Survey in 1909, as a result of studies which were made in response to this commission's request.

It will be seen from Table VI that the Upper bay contains more water at low tide, has a larger tidal prism and has a larger net discharge of water than has any other part of the harbor. The Hudson river is a close second in volume at low tide, but it has a smaller

prism and net flow than the Upper bay. The tidal prism and volume of water at low tide are nearly the same in Jamaica Bay and Newark bay, from which it appears that these bodies of water are almost half renewed at each tide.

In the Lower East river, the tidal prism is one-sixth the volume of water which lies beneath the level of mean low tide and the net ebb flow is about one twenty-seventh of it. Nowhere else in the metropolitan district is the net ebb flow so small in comparison with the tidal prism or volume of water at low tide. Large as is the volume of water in this division, it is evident that there is not a great deal of
27 new water passing through it. In the Harlem also, the tidal prism is large and the net ebb flow small when compared with the volume of water at mean low tide. From these figures, it appears that such refreshing action as the Lower East river and Harlem river receive is due to diffusion with cleaner water at the two ends of these streams and that little renewal occurs by actual displacement with water from a neighboring section. Large though the Lower East river seems to be and swift as are its currents, it has only one-tenth as much net ebb flow as the Hudson.

To facilitate computations which will be described later, the quantities of sewage discharged into the several divisions of the harbor have been converted from gallons per 24 hours to cubic feet per 12 lunar hours. The results are recorded in Table VII.

TABLE VII.

Volume of Sewage Directly Tributary to the Several Divisions of the Harbor.

Division of the Harbor.	Directly tributary, million cu. ft. per 12 lunar hours.	
	Year 1910.	Year 1940.
Harlem river	6.9	17.5
Hudson river	9.2	20.9
Upper East river	1.5	6.9
Lower East river	17.1	31.5
Upper bay	4.4	8.2
Newark bay	0.9	2.1
Kill van Kull	0.5	1.6
Jamaica bay	3.7	11.3

TABLE VIII.

Ratios of the Volume of Sewage Directly Tributary per 12 Lunar Hours to the Volume of Water in the Harbor at Mean Low Tide. The Quantities Given are in Millions of Cubic Feet.

Division of the Harbor.	Water in the division.	Sewage tributary to the division.			
		Year 1910.		Year 1940.	
		Volume.	Ratio.	Volume.	Ratio.
Harlem river	285	6.9	1:41	17.5	1:16
Hudson river	12,330	9.2	1:1350	20.9	1:590
Upper East river	5,512	1.5	1:3675	6.9	1:799
Lower East river	4,174	17.1	1:244	31.5	1:132
Upper bay	12,970	4.4	1:2950	8.2	1:1580
Newark bay	1,542	0.9	1:1680	2.1	1:740
Kill van Kull	728	0.5	1:1470	1.6	1:460
Jamaica bay	2,029	3.7	1:550	11.3	1:180
	39,570	44.2	1:896	100	1:396

28 Table VIII which is prepared from data contained in Tables VI and VII emphasizes the proportionately heavy sewage burden which is now, and in future would be, placed upon the Lower East river. The ratio of sewage to water at mean low tide which was 1 to 244 in 1910 would be 1 to 132 by 1940. A notably low ratio is that of the Kill van Kull which was 1 to 1470 in 1910 and would be 1 to 460 by 1940. This body of water received much of its pollution from neighboring bodies of water. The pollution of Newark bay will increase by direct contributions of sewage until the ratio which was 1 to 1680 in 1910 will be 1 to 740 by 1940 unless measures are taken to keep the sewage out of it.

TABLE IX.

Ratios of the Volume of Sewage Directly Tributary to the Volume of Water in the Tidal Prism. The Quantities Given are in Millions of Cubic Feet.

Division of the Harbor.	Water in the prism.	Sewage tributary to the division.			
		Year 1910.		Year 1940.	
		Volume.	Ratio.	Volume.	Ratio.
Harlem river	148	6.9	1:21.4	17.5	1:8.5
Hudson river	1,697	9.2	1:185	20.9	1:81
Upper East river	1,869	1.5	1:1246	6.9	1:271
Lower East river	552	17.1	1:323	31.5	1:17.5
Upper bay	2,541	4.4	1:570	8.2	1:310
Newark bay	1,071	0.9	1:1170	2.1	1:510
Kill van Kull	150	0.5	1:300	1.6	1:94
Jamaica bay	1,977	3.7	1:540	11.3	1:175
	10,165	44.2	1:229	100.0	1:101

Table IX has been prepared from Tables VI and VII and shows the remarkably small ratios which exist between the sewage and tidal prism in most of the divisions of the harbor. The smallest ratio occurs in the Harlem, 1 to 21.4, although the Lower East river, 1 to 32.3, is very low for the year 1910. In 1940 the tidal prism will be only 8½ times the volume of sewage discharged directly into the Harlem and in the Lower East river only 17½ times the quantity of sewage received.

Unlike the ratio of sewage to water below mean low tide, the relation of sewage to the tidal prism is comparatively large in Newark bay and will be considerable in 1940. This division of the harbor, which was comparable with the Lower East river in Table VIII, resembles the Hudson river, where the pollution is, and probably will remain, large.

The quantities of water passing through each division in their relation to the volume of sewage directly discharged are shown by Table X, which was prepared from Tables VI and VII.

TABLE X.

Ratio of the Volume of Sewage Directly Tributary per 12 Lunar Hours to the Net Ebb Flow. The Quantities Given are in Millions of Cubic Feet.

Division of the Harbor.	Net ebb flow.	Sewage tributary to the division. Year 1910. Volume.	Year 1910. Ratio.	Year 1940. Volume.	Year 1940. Ratio.
Harlem river	15	6.9	1:2.2	17.5	1:0.85
Hudson river	1,087	9.2	1:119	20.9	1:52
Upper East river	.....	1.5	.....	6.9	.....
Lower East river	100	17.1	1:5.9	31.5	1:32
Upper bay	1,283	4.4	1:288	8.2	1:156
Newark bay	105	0.9	1:114	2.1	1:50
Kill von Kull	88	0.5	1:178	1.6	1:55
Jamaica bay	24	3.7	1:6.5	11.3	1:2.1
	2,702	44.2	1:61	100.0	1:27

The small amount of dilution from the net ebb flow which the sewage which was discharged into the Lower East river received in 1910 and will receive in 1940 is even more graphically indicated in this table than in its predecessors. By 1940 there will be more sewage discharged into the Harlem than there will be tidal water passing through that stream. There will be about three times as much tidal water as sewage passing out of the Lower East river. The Hudson river and Upper New York bay alone seem to be comparatively well supplied with water available for flushing purposes.

Table XI shows the number of tons of the various constituents of the sewage based on the composition shown on Page 18, and the volume shown on Page 27. It will be seen that in every important respect, the Lower East river receives a greater weight of contaminating matters than does any other division of the harbor, irrespective of its size. Next comes the Hudson river, followed by the Harlem. The total weight of sewage materials discharged into the Kill van Kull and Newark bay is small as compared with the quantities of polluting matters discharged into the Lower East river.

TABLE XI.

Solid, Organic and Volatile Matters Contained in the Sewage Directly Tributary to the Several Divisions of the Harbor. The Quantities are Expressed as Tons of 2,000 lbs. per 12 Lower Hours.

	1940	629	840	420	420	318	105	420

Table XII, which has been prepared from Table V and VII, shows the weight of sewage ingredients which will be discharged into the harbor in 1910 and 1940, assuming that the sewage is first passed through certain forms of treatment with the object of removing impurities. The efficiency of the treatment employed has been assumed as follows: The screens remove 15% of suspended matter and 10% of organic matter; sedimentation 60% of suspended matter and 30% of organic matter; chemical precipitation 85% of suspended matter and 50% of organic matter; sprinkling filters 90% of suspended matter and 70% of organic matter.

It will be observed that the use of any of these processes would be beneficial, but that the residue to be discharged after screening or sedimentation would still leave very large quantities of pol-
31 luting matter to go into the water. Chemical precipitation and the use of sprinkling filters would probably furnish all the relief needed for as many years as can now be anticipated. As has been shown elsewhere in this report, however, these latter processes are not applicable unless the sewage is carried to some point far removed from its present source for treatment.

7.—Possible Methods of Sewage Treatment.

Early studies made by this commission indicated that excluding from the harbor as much sewage matter as practicable from those parts of Queens, Richmond, Brooklyn and the Bronx which are tributary to the Upper East river and Upper and Lower New York bays, by the employment of local purification works, the water of the inner harbor would be able to assimilate the sewage from those parts of Manhattan and Brooklyn which were closely built up and where sites could not readily be obtained for the construction of purification works of high efficiency. In this belief plans were begun
for collecting the sewage of the Bronx, Queens and Rich-
32 mond and gathering it to a number of conveniently located
central points for treatment.

Two immediate objects were to be attained by these plans. First, the harbor water in those divisions where the works were located was to be kept clean, and, second, the water was to be protected to such an extent as to insure to the inner harbor the largest assimilative capacity practicable.

As the plans progressed, it became evident that a high degree of purification could not be obtained for as much of the sewage as had been expected. To remove a large proportion of the putrescible material from sewage requires works which could not always be situated where engineering considerations alone would have placed them. In such cases land must be procurable at a price which does not unduly increase the first cost of the project. Of equal importance, it is necessary to locate such works in positions where the odors produced will not injure property to such an extent as to give owners of surrounding land valid claims against the city for damages.

Odors from Efficient Processes.—It is needless to deny that all processes of sewage purification cause smells. The fact should plainly be faced that in the removal the ingredients of sewage which are capable of causing the water into which the sewage is discharged to become offensive, objectionable odors may be produced at the works. The danger of nuisance depends partly upon the degree of thoroughness with which the impurities are removed and partly upon the likelihood that the property holders in the vicinity will find the odors seriously objectionable. There are localities in the City of New York and vicinity where objectionable odors are continually produced by manufacturing establishments with little or no complaint from property holders. But these situations are not usually well placed for sewage disposal plants, and it is doubtful of the city would be justified in adding to these odors even if it became otherwise desirable to construct sewage works there. Manufacturing plants which are objectionable, such as slaughter-houses, bone-boiling establishments and fertilizer factories, usually have to move further and further away, as the cities in which they are located grow. Nuisances of this kind become increasingly objectionable as time proceeds, for more and more people become affected and the public becomes increasingly fastidious.

Such strong and offensive odors as are produced by so-called offen-

4513

sive trades are not likely to be produced by sewage works, but the difference is sometimes not great, and the erroneous belief that sewage odors are in some way connected with disease, if not actually a cause of it, adds greatly to the objectionableness of sewage purification plants in any locality.

33 A convenient and economical location for sewage works is hampered by the uncertainty that they will be permanent. Unlike some manufacturing plants, they cannot well be moved in case they produce a nuisance. If they are objectionable at first, they are likely to become more so with the passage of time. Owing to the protest with which a proposal to build a municipal plant for the thorough treatment of sewage probably would be received in almost any part of New York City, this commission has felt compelled to confine its plans largely to works of the simplest character or carry the sewage to a distant point for disposal. In the selection of sites, considerable difficulty has been experienced because of the changing character of many localities. Few parts of New York are permanently constructed. Solidly built-up sections are constantly changing from residence to business occupancy. Suburban districts are rapidly becoming urban, and rural territory is being converted to suburban uses. Each change increases the value of the land. The most rapid developments, and the most uncertain, are sometimes in the very localities where it would be most convenient to build sewage disposal works. Here unimproved property, even farm land, is not infrequently held at a high valuation in the expectation that a strong demand for real estate may set in at any time.

Owing to the facts here mentioned, this commission has not found it feasible to design works which would purify the sewage tributary from the outlying territory to a high degree, and the water which will reach the inner harbor will consequently not have as great a capacity for assimilating sewage as theoretically it should possess.

What is here said as to the nature of the works which it has been feasible to design for Queens, Richmond and the Bronx applies with greater force to the Lower Hudson, Lower east River and Bay Division. The aggregate volume of sewage produced in this division is now great, and thirty years hence will be about double what it is today. Such treatment as it is practicable to accomplish within the territory where this sewage is produced will remove only a small proportion of the ingredients which are capable of reducing the amount of oxygen in the water into which the effluent is discharged. Sprinkling filters, contact beds, sedimentation basins and chemical precipitation plants, cannot be considered for want of land and because of the odors which such works would produce.

The forms of treatment which could be best employed on the shores of Manhattan and Brooklyn would be such as could be carried on with grit chambers and screens.

Grit Chambers and Screens.—In some respects grit cham-
34 bers and screens are well suited to the conditions. Beside being compact, they produce little odor; they can be located partly below ground; they require no extra pumping; they are comparatively inexpensive to operate; they can be employed without

highly skillful supervision, and it is practicable to have many plants of moderate capacity. Against them is chiefly the criticism that they remove only the largest particles of sewage matter and leave the dissolved organic matter and finely divided putrescible materials to pass to the harbor. Notwithstanding this fact, they would serve usefully in attaining the standard of cleanness which the Metropolitan Sewerage Commission has proposed for the water, particularly as respects requirements Nos 1 and 3 of the standard. This standard follows:*

1. Garbage, offal or solid mater recognizable as of sewage origin shall not be visible in any of the harbor waters.

2. Marked discoloration or turbidity, due to sewage or trade wastes, effervescence, oily sleek, odor or deposits, shall not occur except perhaps in the immediate vicinity of sewer outfalls, and then only to such an extent and in such places as may be permitted by the authority having jurisdiction over the sanitary condition of the harbor.

3. The discharge of sewage shall not materially contribute to the formation of deposits injurious to navigation.

4. Except in the immediate vicinity of docks and piers and sewer outfalls, the dissolved oxygen in the water shall not fall below 3.0 cubic centimeters per litre of water.†

Near docks and piers there should always be sufficient oxygen in the water to prevent nuisance from odors.

5. The quality of the water at points suitable for bathing and oyster culture should conform substantially as to bacterial purity to a drinking water standard. It is not practicable to maintain so high a standard in any part of the harbor north of the Narrows or in the Arthur Kill. In the Lower bay and elsewhere, bathing and the taking of shellfish cannot be considered free from danger of disease within a mile of a sewer outfall.

Inasmuch as grit chambers and screens seem to afford the best practicable means available for treating the sewage of Manhattan and Brooklyn locally, it is desirable to consider in some detail how such works would be constructed, how many plants would be required, about where they should be built, what they might cost and how much improvement they would accomplish. In studying these questions, two chief considerations have appeared to be important. First, the outlets from the works should be so built that the treated sewage will be promptly and thoroughly diffused, and Second, the plants should be so located as to permit the sewage to be collected to them without unnecessary difficulty or expense.

Submerged Outfalls.—Owing to the incompleteness of the purification, and the necessity of complying with requirement No. 2 of the

*Report Metropolitan Sewerage Commission of New York, August, 1912, page 70.

†With 60 per cent. of sea water and 40 per cent. of land water and at the extreme summer temperature of 80 degrees F., 3.0 cubic centimeters of oxygen per litre corresponds to 59 per cent. of saturation.

Standard of Cleanness, it would be necessary to discharge the
35 effluent from the plants in such a way as to produce the most immediate disappearance of the sewage which is possible. For this purpose, it is desirable that the outfalls should be near or upon the bottom and be so located that ample and strong currents will sweep by them.

The construction and maintenance of outlets at the bottom of the tidal channels some distance from shore would be difficult. The outlets would have to be so built as to meet all the requirements of the United States Government which has supervision over the maintenance of the channels for the purposes of navigation.

Locations for Outlets.—Bearing in mind the difficulties of construction and maintenance, as well as the advantages of carefully selected places, a number of points have been chosen along the shores of Manhattan and Brooklyn where the sewage, after treatment, could with the greatest advantage be discharged.

The facility with which the sewage could be collected to suitable points for treatment was taken carefully into consideration in selecting the points of outfall. It was thought desirable that the sewage should require the least amount of pumping possible; that the plants should not have to be placed too far below tide level and that the greatest possible normal flow of sewage should be gathered to each plant.

Considerable care has been taken in the designs to make an economical use of land, to provide for adequate inspection and repair, not only of the apparatus, but of the structure itself, to insure light and ventilation and to facilitate the cleaning of the basins and screens and the removal of the impurities from the plant. Numerous forms of grit chambers have been designed and studied. Every form of screen which the experience of other cities had proved reliable and efficient have been considered with the result that the type employed in the new works at Hamburg, Germany, was chosen as the most suitable for these works.

8. Plan for th Disposal of the Sewage of this Division.

Investigation having shown that it will be impossible to discharge all the sewage into the water in the vicinity of the territory where it is produced, even after such purification as is practicable, it becomes necessary to consider where it can be taken and what can be done with it.

Amount of Sewage to be Taken Away.—It will not be worth while to take a small amount of sewage from the inner harbor. To accomplish much benefit, the volume will have to be large both actually
and in relation to the total quantity produced in this division.
36 If possible, it should be taken from a part of the harbor which needs relief both on its own account and because of its influence on adjoining sections. As far as practicable, the sewage should be collected from a region of dense population in order that the length of the sewers shall be no greater than necessary. For the

same reason the distance from the central point of collection to the point of disposal should be as short as possible.

This report shows that the greatest burden of pollution which is placed upon any large portion of the harbor is discharged from Manhattan and Brooklyn into the Lower East river. Here within a distance of 4 miles, about 200,000,000 gallons of sewage are discharged every 24 hours from about 50 outlets located along the crowded shores. Not only is the volume of sewage large, but, as shown elsewhere in this report, the waters are peculiarly unsuited to receive it.

If this polluting material can be removed, the waters in the immediate vicinity will be improved and the excessive burden of pollution now put upon the whole inner harbor will be relieved. An improvement of the waters of the Lower East river is desirable for the help it will give in disposing of the sewage which, in accordance with the commission's plans already announced, will be brought to Ward's Island.* At Ward's Island the large quantity of sewage which will be brought from the Harlem river will be passed through settling tanks and discharged into the deep waters of Hell Gate, and reliance must be placed upon the digestive capacity of the waters to oxidize the liquid organic matters.

If 200,000,000 gallons of sewage per day can be kept out of the Lower East river, the ratio of sewage to water in that section will improve sufficiently to meet all requirements of this commission's standard of cleanness for the present. The ratios of water to sewage which will exist in the Lower East river are given in Table XIII.

TABLE XIII.

Ratios of Sewage to Water in the Lower East River, if 200,000,000 Gallons of Sewage per Day Are Kept Out of these Waters.

Year.	Sewage to water at low tide.	Sewage to tidal prism.	Sewage to net ebb flow.
1910	1 to 1090	1 to 204	1 to 30
1940	1 to 178	1 to 33	1 to 5.6

Direction in which to Take the Sewage.—There are not many directions in which the sewage can be taken. It would be impracticable to carry it north into Westchester County, for the land there lies at too great an elevation. It would be impossible to carry it west because the people of New Jersey would object to receiving it. The idea of discharging it into the Hudson river cannot be entertained, for if this were done that stream would become too heavily polluted. Sentimental considerations require that the Hudson shall not be made a receptacle for the sewage from other parts of the harbor.

37

It would not be feasible to carry the sewage to Long Island sound;

* Preliminary Report IV. Study of the Collection and Disposal of the Sewage of the Upper East River and Harlem Division, July, 1912.

the distance would be too great, the volume of water there available would be insufficient, the danger of polluting extensive shellfish beds would be large, and the risk of contaminating the shores in the vicinity of villages, towns and country estates too imminent.

The sewage could not be taken east on Long Island, except to a distance of 30 or 40 miles, for its disposal would be certain to produce nuisance and, consequently, serious injury to property already occupied for residence purposes or likely soon to become valuable for this purpose. Furthermore, opportunities for the disposal of the effluent of treatment works are lacking on Long Island, the north shore of which is deeply indented with bays and, for the most part, high and rocky, and the south shore bordered with broad, shallow bays and marshy islands, where the flow of tidal water is relatively slight.

Staten Island Not Suitable for Very Large Sewage Works.—To the southwest of this division lies the Borough of Richmond, or Staten Island, and much sewage could be brought there for treatment as far as engineering considerations are concerned. There are several thousand acres of marshy land on the west side of this island bordering the Arthur Kill which might be employed for sewage disposal, provided no nuisance was produced.

The sewage could be taken to the disposal works by a tunnel which could be driven beneath the waters of Upper New York bay to the north shore of Staten Island, and thence through the high land to the low-lying area near the Arthur Kill. The Arthur Kill has been dredged for the convenience of ships and could receive a well purified effluent, although owing to its small volume of flow and the oscillating effect of the tide, the capacity of the Arthur Kill for unpurified sewage is comparatively small. If the sewage could not be purified sufficiently to discharge the effluent into the Arthur Kill, it would have to be carried by tunnel eastward from the treatment works to the waters of Lower New York bay.

It is probable that treatment works capable of purifying the sewage to such an extent as would permit the effluent to be discharged into the Arthur Kill would be impracticable on Staten Island. Apparently some oxidizing process, either sprinkling filters or possibly contact beds, would have to be employed. It is probable that
38 if either of these processes were used to treat the quantity of sewage which would have to be dealt with, not less than 200,000,000 gallons per 24 hours, with a certainty of more later on, objectionable sanitary conditions would be produced. The sewage would be septic and, consequently, likely to produce odor when brought into contact with the air either in the fine spray necessary in sprinkling filters or in the large areas of surface exposed by the broken stone of contact beds. The likelihood of trouble from flies, a frequent any annoying feature in sewage works, should also be considered. The peculiar mist which sometimes hovers in calm weather over extensive areas of sprinkling filters would prove a source of gave concern to property holders, even at a considerable distance from the works. Before the authorities of the Borough of Richmond would give their consent to receiving the sewage of this division in

that borough for disposal, it is probable that they would insist upon more assurance of immunity from nuisance than safely could be given.

Added to the sanitary difficulties which would attach to the disposal of the sewage by works upon Staten Island is the consideration of cost. It would be expensive to carry the sewage of this division to Staten Island and there dispose of it. The tunnels would be long and, in places, very deep. The foundations for the works on the lowlands in the western part of Staten Island might prove difficult of construction. The outlet tunnel for the effluent would be long and costly.

Objections to Collection at Barren Island.—Two other possible means of disposing of the sewage of this division remain to be considered. First, collection to the vicinity of Barren Island, near the mouth of Jamaica bay, and treatment there, with a discharge of the effluent at sea. Sanitary considerations, such as have been mentioned in connection with the possibility of carrying the sewage to Staten Island, would weigh heavily against purifying the sewage any more completely than is absolutely necessary at this point. The outlet would therefore have to be long enough to carry the sewage far from shore.

Unless the sewage was purified in bacteria beds, it would be necessary to extend the outlet some miles out to sea beyond Rockaway Point in order to make sure that the sewage would not be carried back to the land by the wind and tide, and there are practical difficulties in the way of doing this. The necessary tunnel for this purpose would be very difficult to construct. It would have to be at least 75 feet below the surface of the water, in order to cross well beneath the deep, swiftly-flowing channels of Rockaway inlet. The water at this point is between 30 and 40 feet deep at low tide. Proceeding seaward it would not be found desirable to approach much nearer the surface with it. The point of outfall should probably be
39 located about 2 miles from shore. This would be an unfavorable location for an outlet crib or other permanent structure, for it would be exposed to the full force of the Atlantic ocean and the shifting sands. This project thus has weighty arguments against it.

Advantages of Disposal at Sea.—The sewage from the Lower East river section can be taken directly to the sea, and this is the plan which the commission recommends. In accordance with this plan, central collecting points will be established which will be tributary to a general central station, to which latter point will be gathered such part of the sewage as needs to be carried to a distance. Pumps will be located at the central station and from it a main will run directly to an outfall island to be built about 3 miles from land on a sandy reef. This reef is one of a series of shallow areas, interspersed with channels, which once formed the bar to New York harbor. It lies slightly to the west of an imaginary line between Sandy Hook and Rockaway Point. The outfall will be about 13 miles from the New York City Hall, 6 miles from the Narrows, over 4 miles from Sandy Hook and about 3 miles from Coney Island. The point selected for this island is shown in Plate I, following page 48.

As much sewage as it is necessary to carry to a distance from the Lower East river, Hudson and Bay Division can be taken to the island for disposal. As time proceeds and the quantity of sewage increases, the main sewer can be duplicated and the provisions for treating and discharging the sewage at the island can be enlarged.

A large part of the sewage of this division is now discharged into the waters of the Lower East river. If this sewage is taken away for disposal, it will for some time be possible to discharge the sewage from the rest of the division with no other treatment than screening and passage through grit chambers. The water of the Hudson will be capable of assimilating the sewage produced on the west side of Manhattan Island and the water of the Upper bay could take the sewage produced along the Brooklyn water front from Governors Island southward.

All the sewage from this division, except that part which is taken away, should be passed through grit chambers and screens and, where feasible, the dry weather flow discharged through submerged outlets. In course of time, if the quantity of sewage from this division, as well as from that part of the Upper East river and Harlem Division which would be concentrated at Ward's Island, increases to such an extent as again to place an excessive burden upon the waters of the East river, the sewers can be extended and finally the Ward's Island works can be connected with a main sewer to the artificial island for disposal.

40 The plan of relieving the harbor of its heaviest burden by at once taking to sea a large part of the sewage which flows to the Lower East river and increasing the scope and magnitude of the work as necessity arises, appears to this commission to be a necessary and sufficient solution of the problem. In no other way can the sewage be disposed of with so little chance of danger or offense. The project has the advantages that it will afford, at minimum expense, all the relief that is needed for the present and is capable of expansion in the future.

There are no selfish industries in the vicinity and no currents which would carry any of the sewage to a bathing beach. The sewage will not be exposed long enough to the air to cause annoying odors to be given off and there will be no opportunity for flies to breed.

The plan is in accordance with the best engineering precedent. There is no feature connected with it which is untried or experimental. It avoids offensive, complicated and uncertain processes of purification. It is based upon a careful consideration of the needs of the whole harbor. It leaves the waters of the inner harbor in a sufficiently improved condition for the assimilation of such sewage as cannot be kept out of the waters without wellnigh prohibitive expense.

Ultimate Digestion by the Sea Water.—The project for carrying a part of the sewage to sea contemplates the treatment of the sewage at the island and the ultimate digestion of the liquid organic matter of the sewage by the sea water. Responsibility for the disposal

of the sewage cannot cease until all the ingredients are rendered harmless and inert. It is important that the sewage shall not flow from the outlets as a coherent mass and that none of its elements shall be carried to the inner harbor or find their way, under the influence of wind or tide, to the shore. Accumulations of solid matter injurious to navigation must not be permitted to occur, nor must odors or flies or other objectionable features too commonly associated with sewage disposal works exist to mar the natural attractiveness and healthfulness of that part of the ocean where the outlet is located.

The liquid sewage matters will have a strong avidity for oxygen and will be rendered inert by the oxygen-saturated sea water with which it comes in contact. The great amount of water available at the point of outfall will have an abundant capacity to digest the liquid sewage.

At first the form of treatment needed at the island will be settlement in tanks perhaps aided at times by precipitants. In addition, it may be practicable to disinfect the sewage and produce a considerable amount of oxidation by the addition of bleach or electrolytically produced hypochlorite.

If at any time in the future it becomes desirable to completely purify the sewage, no such favorable location for the necessary
41 works can be found in the metropolitan district than this artificial island. Owing to the shallowness of the water and the ease with which filling can be obtained, land can be made here for less money than an equal area can be bought on shore at any point not more distant from the New York City Hall.

In addition to the sewage from the Lower East river section, it will ultimately be feasible and desirable to send the sewage of the western Jamaica bay sub-division to the island for disposal. This would make it unnecessary to construct treatment works at Barren Island as proposed in an earlier report of this commission*

9.—Collecting the Sewage to the Outlet Island.

Sub-division of the Territory.—The territory included in the Lower Hudson, Lower East River and Bay Division has been separated by this commission into 32 sub-divisions for the purpose of laying out the works which will be necessary for the sanitary disposal of the sewage, and each sub-division has been given a number. The sub-divisions numbered 1 to 12, inclusive, comprise that part of Manhattan which is naturally tributary to the Hudson river. Sub-divisions from 13 to 26 are in Manhattan and Brooklyn, bordering upon the Lower East River. Sub-divisions 27 to 31 are in Brooklyn and border on the Upper bay. Sub-division 32 borders on the Narrows and Gravesend bay.

The sub-divisions vary in size and in quantity of sewage which they produce. The boundaries which have been approximately established are intended to show the limits within which it will be feasible to collect the sewage to a central point on the water front in each

*See Preliminary Report III.

sub-division. The central points are usually near existing large sewers and, as often as practicable, at places which are favorable for a prompt admixture of the sewage effluent with the harbor water.

As stated elsewhere in this report, the dry-weather flow of sewage, after collection to a central point in most of the sub-divisions, should be passed through grit chambers and screens and so discharged into the water as to insure prompt diffusion.

The dry-weather flow of sewage produced in the six following sub-divisions bordering upon the Lower East river should not be discharged into the neighboring waters, but should be gathered to a central point and thence carried to sea: In Manhattan, 13, 14 and 15, and in Brooklyn, 24, 25 and 26.

The method of collection in those subdivisions from which the sewage is to be carried to a distance may or may not be the same as in those sub-divisions from which the sewage will be discharged into the neighboring waters. There are various ways in which
42 the sewage can be collected. One method may be described by way of illustration.

The dry-weather sewage can be collected by marginal sewers to a central point in each sub-division and there passed through grit chambers and screens. Passing beneath each central collecting point will be a deep-lying intercepting sewer which will receive the sewage after it passes through the screens and grit chambers. Storm water in excess of twice the dry-weather flow will pass by overflows at each outlet directly to the river. Further details of this plan follow.

The Necessary Marginal Sewers and Interceptors.—Each central collecting point will have storm overflows, regulators and tide gates so arranged as to discharge directly into the neighboring waters the excess flow of sewage during periods of rainfall. The interceptors are intended to be large enough to accommodate twice the mean rate of flow during periods of dry weather. The maximum rate of dry weather flow is assumed to be about one and one-half the average rate per 24 hours. This will permit the interceptor to carry off some of the first flush of storm water even if it reaches the plant during the hour of maximum sewage production.

The marginal sewers required to collect the sewage from the present sewers to the central points in each sub-division will lie as close to the surface of the ground as physical conditions permit.

The interceptors will be situated at a considerable depth and be so located as to avoid as far as possible difficulties of construction. It will probably be necessary to construct the interceptors by shield tunneling. In making the plans and estimates, careful attention has been given to the information available concerning the geology of the territory passed through as determined by borings made by the Public Service Commission, Board of Water Supply and others.

The Manhattan Lower East Side Sub-divisions.—The interceptor from sub-division 13 will run from a screening plant situated near Roosevelt St. parallel to the shore to Corlears Hook, where the sewage will empty into a siphon and be carried to Brooklyn. This South Manhattan interceptor will be 5′ 9″ in diameter.

A second interceptor, which may be termed the North Manhattan

interceptor, will run from East 14th St. southerly to a siphon to Brooklyn which begins at Corlears Hook. The size of the North Manhattan interceptor will be 9′ 6″ from the screening plant for sub-division 15 to the screening plant for sub-division 14 at De Lancey Slip, where it will increase to 10′ 10″ in diameter before joining the siphon. The North Manhattan interceptor will be large
43 enough to permit an extension to be made in it, so as to take in the sewage of sub-divisions 16, 17 and 18 in course of time. Profiles of the Manhattan marginal sewers and interceptors are shown on Plate II, following page 48.

The total quantity of sewage to be taken from sub-divisions 13, 14 and 15 is estimated at 99,000,000 gallons per 24 hours in the year 1915. The estimated population for the same year is 680,500, and the area from which the dry-weather flow will be taken is 1,737 acres.

The Siphon from Manhattan to Brooklyn.—A siphon will be required to carry the sewage from Manhattan to Brooklyn beneath the lower East river. The point selected for the crossing is at a narrow part of the river where solid rock may be anticipated. The siphon which will be required to take the sewage produced in 1915 should have a diameter of 8′ 9″. The depth will be 110 feet beneath the surface of mean low water. The siphon will be 2,300 feet long and extend from Corlears Hook to South 8th St. When the North Manhattan interceptor is extended so as to take the sewage from sub-divisions 16, 17 and 18, it will be necessary to build a second siphon. This can be laid parallel to the first. It is desirable that the siphons needed at first shall not be too large, in order that the velocity of flow may be sufficient to prevent deposits taking place. The velocities considered suitable for the first siphon range between 2 and 5 feet per second.

The Brooklyn North Western Sub-divisions.—That part of Brooklyn which will be tributary to the main sewer to the sea will be treated in a way similar to that described for collecting the sewage from the lower east side of Manhattan. The quantity of sewage to be taken from this part of Brooklyn will be a little larger than the quantity from Manhattan, or about 104,000,000 gallons per 24 hours in 1915. The estimated population tributary in Brooklyn will be slightly larger, or 732,313, and the net area more than three times as large, or 5,790 acres.

The siphons from Manhattan will empty into an interceptor on the Brooklyn shore which will run from a central collecting point at South 5th St. for sub-division 24 to a general pumping station at Wallabout St., near the head of Wallabout canal. This interceptor will be 5′ 3″ in diameter before meeting the siphon and 10′ 3″ from the junction with the siphon to the pumping station. This may be termed the North Brooklyn interceptor. In course of time, if it becomes necessary to bring the sewage of sub-divisions 19, 20, 21, 22 and 23 to the general pumping station, this can be done by running another interceptor to the central collecting points in those sub-divisions. It appears to be unnecessary to make further provision for the future at the present time.

44 From sub-division 26 in Brooklyn, which is opposite the lower end of Manhattan, an interceptor should be built to the general pumping station. The central collecting point in sub-division 26 will be near Adams Street and the interceptor leading therefrom should be 4′ in diameter. This is estimated to be of sufficient size to take the flow from sub-division 27 in the future. At Hudson Street, this interceptor would receive the sewage collected from sub-division 25. Running around the Brooklyn Navy Yard, this South Brooklyn interceptor should have a diameter of 9′ 6″ to the general pumping station. Profiles of the Brooklyn marginal sewers and interceptors are shown on Plate III, following page 48.

The General Pumping Station.—The sewage collected at the general pumping station, amounting to about 200,000,000 gallons a day, will have been passed through grit chambers and screens and will be in reasonably fresh condition. It will all flow to this point by gravity. The pumps will be required to raise the sewage from an elevation of about 27 below mean tide and pump it under a head of about 45 feet to the artificial island at sea. The distance to be pumped will be about 11.8 miles and the head to be overcome will be that which is necessary in order to raise the sewage from the level at which it is delivered to the pumps to the level of the tanks where it is to be treated on the island, plus the head required to overcome the frictional resistance offered to the passage of the sewage through the long main. The pumps can be operated by steam, oil or by purchased electric current. It would seem feasible and desirable to drive the pumps with electric power to be obtained from burning the solid refuse of the city in destructors, as is commonly done in England and in certain large cities of Europe.

The Sewage Main to Sea.—The force main through which the sewage will be pumped to the island will be built, for the most part, in tunnel. There will be three shafts, so situated as to permit the work of construction being pushed with expedition and economy. The internal diameter of the completed main will be 12′ 10″ from the pumps to a point near Sheepshead bay, where it will be increased to 14′ in order to accommodate the sewage from the western part of the Jamaica Bay Division. A profile of the outfall main is shown on Plate IV, following page 48.

The estimates given below are based upon the work already outlined, but since the sewage main will pass comparatively near Jamaica bay, it may be desirable to modify the plan which this commission proposed for the Jamaica Bay Division* to such an extent as to permit the main to take to the island the sewage which it has been proposed to collect from Brooklyn to Barren Island for
45 treatment and disposal. The advantages to be gained by this change are (*a*) reduction in cost over the Barren Island project and (*b*) avoidance of the necessity of constructing a sewage disposal plant at the entrance of Jamaica bay. By adding the sewage of the western Jamaica bay sub-division to the sewage of Manhattan and Brooklyn which is pumped to the island, the disposal works will

* Preliminary Report III, November, 1911.

be centralized and questions of administration and maintenance will be simplified.

The Western Jamaica Bay Sub-division.—The sewage from the western part of the Jamaica Bay Division will be collected at two central pumping stations, one at Hendrix Street and the other at Flatlands Avenue. From the eastern pumping station, an interceptor 9′ to 9′ 6″ in diameter will extend for 2.6 miles to a second pumping station at Flatlands Avenue. From this point the interceptor, enlarged to 11′ 4″ in diameter, then 11′ 8″ and finally to 12′ in diameter will extend to Nostrand, where it will be joined by a small interceptor of 27 inches from the present sewage disposal works for Sheepshead bay which will be converted into a pumping station. The interceptor enlarged to 12′ 4″ will end at a pumping station to be located at Ocean Parkway and Avenue W. This last pumping station will discharge the sewage into the main which runs to the island.

A pumping station to be located at 86th Street and Avenue V in Bensonhurst will discharge through a 4′ interceptor to the pumping station which will serve the western part of the Jamaica Bay Division. The sewage of Coney Island will be pumped from the present plant known as Caisson No. 3 directly to the main sewer.

The quantity of sewage from the western part of Jamaica bay will be about 47,000,000 gallons per day in 1915. The population will be about 343,000 and the area served 19,000 acres.

The Artificial Island.—The tunnel to the island will be 14′ in diameter and constructed at a depth of about 60 feet, the material to be penetrated being sand. It will be possible to construct the tunnel with two headings, one from the shore and one from the island, the two meeting and being properly joined.

The point selected for the island has been carefully chosen with reference to economy of construction, resistance to the destructive influences of tidal currents and storms, freedom of obstruction to the free flow of tidal water in and out of the harbor and absence of sanitary objections.

The location lies to the north of Sandy Hook and to the south of Coney Island. Its position is latitude 40 degrees 31½ minutes and longitude 73 degrees 58½ minutes. The water within a mile from the island in all directions varies between 7 and 40 feet in depth, the average being about 20 feet at mean low tide.

46 The plan of the island is approximately rectangular, the seaward side being rounded. The area at the start will be about 20 acres. This can be extended as required. The general plan of the island is shown on Plate V, following page 48.

The outer face of the island will be a wall of rip rap composed of large pieces of broken stone carried to the site on boats and laid upon the hard sandy bottom. It is expected that some settlement will occur, due to the water cutting sand away from under the stone. When sufficient rip rap has been placed to stop this action of the water, no more settlement is to be expected. The main bulk of the island will be composed of sand supplied from a suction dredge, which will take its supply from the bottom of the sea in the vicinity.

The height of the island above mean low water will be about 18 feet. The length will be 1,300 feet and the width 1,000 feet. The side of the rip rap wall which is exposed to the sea will have a slope of 1 vertical upon 3 horizontal and the other sides will have a slope of about 1 on 2. The cost of constructing the island has been estimated at about $615,000.

The landward side of the island will be provided with a quay wall for the accommodation of vessels engaged in taking supplies and other materials to and from the island. Shelter from the sea will be provided by a breakwater, which will enclose a small harbor.

The island will contain a plant of settling tanks in which the sewage will have an opportunity to deposit its solid matters during a period of about two hours. These tanks will be of modified Dortmund tank construction, similar to those recently constructed at Toronto, Canada. Provision will be made for treating the sewage if necessary with a coagulant before passing it into the tanks.

After treatment, the sewage will be discharged through a number of outlets arranged radially on the seaward side of the island. If desirable, it will be feasible to pump sea water into the sewage and provide for the mixture of the two before the discharge takes place. Such admixture would facilitate the immediate diffusion of the sewage in the sea water, but the active agitation and free movement of the great volume of water in the vicinity of the island will probably make the preliminary admixture of sea water and sewage by pumping unnecessary.

The material which settle- out in the tanks will be carried to sea in boats and dumped.

Cost.—This project will require the construction of about 5.3 miles of marginal sewers in Manhattan and Brooklyn and about an equal length of interceptors in these two boroughs. The siphon from Manhattan to Brooklyn will be a little less than a half mile long. The main from the pumping station to the island will be about 13 miles long. If the Jamaica bay sewage is brought to the island, about 2 miles of collectors and 7 miles of interceptors will be required in addition.

47 & 48

Th studies which have been made indicate that the total cost of construction would be about $22,874,000, including $4,072,000 for the Jamaica Bay Division. The fixed charges, including sinking fund and interest, would be about $1,157,000, allowing $206,000 for the Jamaica Bay Division. The total maintenance and fixed charges would amount to about $1,803,000, including $286,000 chargeable to the Jamaica Bay Division.

I.

Studies for Grit Chambers, Screens, and Regulators.

The grit and screen chambers could be constructed, beneath the level of the street pavements, but in all cases it would be desirable, and in some instances probably necessary, to provide a super-structure. All the plants would be small and where a building over them was necessary, it could be made architecturally unobtrusive in appearance. If the sewage were collected by a combined system of sewage, the plant would require to be provided with means for separating a part of the storm water and the latter could discharge directly to the water. It would be feasible to pass three times the dry weather flow of sewage through the plant during periods of storm, and if this were done the work of the water from the streets would be provided for in the works. A study for a grit chamber is shown in Plate VI, following page 52.

In addition to the provisions for avoiding an excess of storm water, the principal features of the plants would be a grit chamber and screens, pumps, tide gates and submerged outfalls. The grit chamber would be essentially an enlargement of the sewer and be of such design as to provide for the slowing of the sewage flow as much as practicable. A prominent feature should be the means for cleaning out the grit and other solid matters which would be deposited. Elaborate methods for cleaning grit chambers are employed in some European sewage disposal works, but simple and effective dredging apparatus appears to be preferable. The material dredged from the grit chamber should be dumped into suitable carriers. These carriers, which could also carry away the screenings would operate electrically. They should convey the materials to some dock or pier where a vessel could carry the impurities to sea or the inflammable part of the refuse could be disposed of by burning.

On passing from the grit chamber the sewage should be screened. After considering many types of screens employed in Europe and America, including those capable of removing the utmost quantity of suspended matter possible, it seems best to employ a moving bar screen with openings of about 4/10 of an inch. The type used in the new installation at Hamburg, Germany, appears to be suitable for New York. This screen consists of an endless belt of bars arranged at an inclination to the flow of the sewage. The sewage passes between the bars and leaves the solids, which are caught and carried upward on the screen belt as it slowly revolves. The screens which are carried up out of the sewage are removed from the belt by means of brushes and a hose and discharged upon a belt conveyor
50 which carries the material to a car which stands in readiness.

The size of the openings between the bars of this screen do not necessarily indicate the size of the particles removed from the sewage. If the screen is revolved very slowly, its effectivness in re-

moving suspended matter will be increased. After the sewage leaves the screens, it passes to the pumps. The pumps should be of the centrifugal type directly connected to motors. The pumping equipment should be in duplicate, as should the screens and grit chambers.

Leaving the plant, the sewage should flow under slight pressure to the outer ends of piers, where it would pass downward through a pipe to the bottom and thence outward into the current for discharge. The tide gates should be located near the point where the sewage is passed through the grit chambers and screens.

In order to consider the practicability of installing grit chambers and screens, locations have been tentatively chosen for the outlets and the approximate locations of the works fixed. The next step was to separate the division into subdivisions and select a few of those for more detailed study. The collecting system in each subdivision was assumed to be already complete save for such interceptors and other large sewers as might be needed to gather the sewage which was now passing to the harbor through many outlets to the central plants. Four sub-divisions were selected for special study, in which the topography and other conditions were dissimilar.

Sub-division No. 5.—One of the sub-divisions was on the Hudson river shore of Manhattan Island, between the northern end of Central Park and the Riverside Park. The sewage from this area is produced by a high-class apartment house population. The topography is such that no difficulties to drainage exist. The site for the plant was in Riverside Park at 96th Street. The quantity of sewage was 25.4 million gallons per 24 hours during dry weather and three times this quantity was provided for at the plant. The storm water outlets were intended to be carried to the end of the West 97th Street pier and were given a capacity of 270 million gallons per day. The cost, including excavation, sub-structure, super-structure and 15% for contingencies, was $89,000 for the plant. The outlets for the dry weather flow would run to a point 300 feet off the pierhead and would cost about $24,200. The outlets for the storm water overflow at the pierhead would cost about $37,000. Total, $150,200. This estimate does not include the cost of intercepting the sewage and delivering it to the treatment plant.

Sub-division No. 14.—The second sub-division studied would have a treatment plant at Broome Slip, near the East river. In this case the area drained is occupied by a crowded tenement house
51 population. There would be difficulty in collecting the sewage to the plant, since the ground is, for the most part, low. The works would have a total capacity of 93 million gallons, which would be about three times the dry weather flow. Storm water in excess of this quantity would be diverted directly to the East river, and the rest raised by pumping. In all other essentials the plant would be similar to that at 96th Street. The estimated cost, including excavation, sub-structure, super-structure, machinery and 15% for contingencies, is $133,000. This figure does not include the cost of collecting the sewage and delivering it to the plant or of conveying it from the works to the outlets.

Sub-division No. 19.—A third sub-division studied contemplates the location of a plant at Orchard Street, Astoria. In this case the capacity would be 87 million gallons per day or three times the dry weather flow. Difficulties of drainage due to low-lying land would require pumps to lift the low level sewage to the works. The estimated cost for excavation, sub-structure, super-structure, machinery and contingencies would be $81,700, exclusive of the cost of delivering the sewage to the plant or conveying it thence to the outlet.

Sub-division No. 30.—A fourth location for a grit chamber and screening plant would be at the foot of 64th Street, Brooklyn. The capacity in this case would be 68 million gallons per day or three times the dry weather flow. The cost, including excavation, sub-structure, super-structure, machinery, connection with sewer and 15% for contingencies, would be $147,000, exclusive of cost of conveying the sewage from the plant to the outlet.

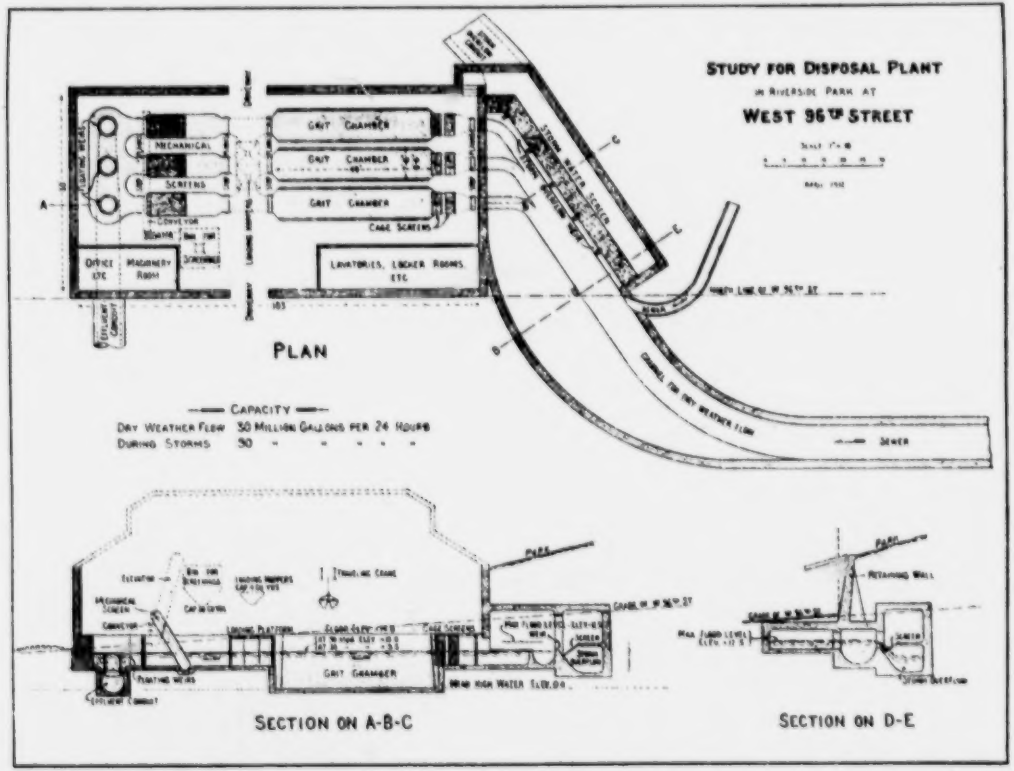
If there was one grit-chamber-and-screening plant, in each sub-division, the total number would be thirty-one. If their cost is indicated by the studies made for the four sub-divisions mentioned, the total outlay for them would be in the neighborhood of $710,000. This would exclude land and the outfalls.

Heavy Rainfalls.—Inasmuch as the frequency with which the storm overflows would come into play should be considered, studies have been made of the records of precipitation as kept by the United States Weather Bureau. The maximum precipitation in each month for 5, 10 and 60 minute periods from April 1, 1896 to January 1, 1912, and for 15, 30 and 120 minute periods from January 1, 1903, to January 1, 1912, have been examined. The results for the months of December, 1895, January, 1897, and February, 1898, are missing. The tabulations of the Weather Bureau were for the most severe single storm each month and it is possible that the actual frequency would slightly exceed that indicated by these diagrams. But the difference would not be so great as to be of consequence in any provision for storm water overflows.

On applying the results of these studies of rainfall, it appears that a volume of storm water in excess of three times the dry
52 weather flow would occur on an average once in about 3½ months and six times the dry weather flow would be received about once in ten months. Ten times the dry weather flow would happen about once in three and one-half years, and the maximum flow for which the plant would be designed, above which the sewer would be surcharged, would occur about once in 6½ years.

Annual Costs.—The annual costs of operating the grit chamber and screening plants have been approximately estimated. These charges do not include fixed charges required on account of intercepting the dry-weather flow nor do they cover the provision of storm water overflows or submerged outlets. The solid matter removed by the basins and screens would be carried, according to these estimates, to the nearest public dump: from the two Manhattan plants by motor trucks serving about four plants each; from the Astoria plant, by chutes to a steamer; from the 64th Street, Brooklyn, plant, it would be conveyed for a short distance to the water

front. In each case, it would be taken to sea by a steamer for disposal. Still better, the screenings could be burned.



The amount of sludge produced has been assumed to be one ton per million gallons of sewage. These estimates are based on the assumption that a sufficient number of plants are in operation to warrant the use of a sludge steamer without which the sea discharges per ton would be much greater than the amount here indicated.

Estimates of Annual Expense of Grit Chamber and Screening Plants.

II.

Studies for Tide Gates.

Most of the grit chambers and screens would be situated so close to the tidal level that the plants would be in danger of flooding through the outlet pipes if provision was not made to prevent it. To prevent flooding, tide gates would be needed and these should be of the most reliable form procurable.

Many forms of tide gates have been considered by the Commission, the experience of engineers in America and England being taken carefully into account, and special attention being paid to the best current practice in this direction in Holland. As a result, it is believed that although tide gates are not always reliable, a form can be designed which will satisfactorily answer the requirements of the situation.

Tide gates in common use are of three general types: flap valves, swinging gates and sluice gates.

Flap Valves.—Flap valves which swing on a horizontal hinge are most often used on sewer outlets of moderate or small size, although good examples of this type exist in some large sewers. At Washington, D. C., gates are used which are made of Georgia pine 5 feet 6 inches wide by 8 feet high and at Philadelphia there are gates of yellow pine 18 feet wide and 2 feet high. With large sizes, two flap valves are usually placed in the gate, one above the other, as at Aberdeen, Scotland, and Atlantic City. At Aberdeen, the balanced flaps are of cast iron and the opening for discharge is 5 feet 6 inches by 6 feet 6 inches.

For the flaps to work freely, they should hang loosely from links, as at Atlantic City, or from easy-working hinges. Composition bearings are desirable in order to avoid corrosion. At Washington the hinges and bolts are of bronze. A ring of rubber set into the gate forms a watertight joint, with a cement seat. At Philadelphia, a rubber gasket is provided which bears against a copper seat. To aid in securing a tight closing of the valve, the seat is usually inclined to the vertical; 1 in 6 at Washington, and 30° at Philadelphia.

If the sewer is of large size, the weight of the flap gate may be so great as to interfere with the free discharge of the sewage. Gates which swing on a vertical axis have an advantage over flap valves in this respect. The leaves of such gates are usually made of wood, white pine being used in some cases, as in Boston. To insure tight closing, a counterweight may be hung on a chain passing from a rod projecting from the outer end of the gate to a point above the hinges. In a patented device used in Boston, the hinges are slightly inclined so as to offset in part the buoyancy of the gates which tends

54 to keep them open. To further insure tightness in the Boston gates, a lead weight which is moved by gravity in a closed sheath attached to one leaf of the gate is hung on a chain which passes over a pulley and then horizontally to a post on the other leaf. The counterweight is thus kept out of the sewage. A rubber strip is attached to the bevel end of one leaf and to each leaf is at-

tached a rubber strip opposite the seat to insure tight closing. A study for a flap tide gate is shown in Plate VII, following page 54.

Sluice Gates.—Sluice gates, or penstock gates as they are often called in Europe, are sometimes employed to more certainly secure protection from back water. In some instances, as at Kings Lynn, a sluice gate is placed behind a flap valve for the added security which is thus afforded. Sluice gates for this use are generally of cast iron and are raised by a screw. As the weight is considerable, a counter-weight is often provided, as in the case of a flushing gate in Boston. If the gate is double, it will facilitate opening, the lower half being raised first. An added advantage in having double gates lies in the saving which they afford in head room in case the lower gate is of large size.

Large sluice gates should be mechanically operated, as at Portsmouth, where turbines actuated by the sewage are used to operate twelve 3 foot by 3 foot 9 inch gates. Auxiliary inlets to the turbines are there first opened by hand, although it would seem possible that the operation could be entirely automatic.

At Aberdeen there are two penstock gates, one closing against the tide and one against the sewage, with a flap valve between. They are about 6 feet 6 inches square, with gun metal facings. Each is operated by a 30-inch hydraulic cylinder using water pressure of 35 pounds per square inch.

If properly designed and regularly inspected, flap valves are an efficient means of excluding tide water from sewers, but there is always some chance that wood and other floating substances may become caught in the opening and prevent the flap from closing tightly. The Washington gates afford an excellent example of the reliability and economy of this type of tide gate. Sixteen of these gates have now been in service seven years without any expenditure for repairs.

For very large sewers, swinging gates are to be preferred to any other means of excluding tide water. Sluice gates are more certain than flap valves and swinging gates to close tightly, but they are costly and cumbersome, both to construct and operate. Where the tidal ranges are great, they have advantages over other forms on account of their strength and compactness. In all cases tide gates should be built in duplicate.

III.

Studies for Submerged Outfalls.

The value of submerged outfalls lies in the fact that they materially aid in bringing about a prompt and thorough mixture of the sewage and water into which the sewage is discharged.

Preliminary to describing a form of construction which appears to be practicable for submerged outlets in the sub-division with which this report deals, it is desirable to consider the circumstances under which sewage will and will not mingle with the surrounding water.

Dispersion and Diffusion.—The terms dispersion and diffusion are sometimes used interchangeably in describing the intermixture of sewage and water, although, strictly, there is a difference in their meaning. The term dispersion implies a separation and scattering, particularly of solid particles, while diffusion refers especially to that form of rapid and intimate mixture which is most often considered as taking place among gases. Both dispersion and diffusion are necessary for the disappearance of sewage. The solids must become scattered and the liquids must become diffused. When solids accumulate, they may form deposits or else masses which are visible at the surface. Unless the liquids become diffused, they do not come into contact with the oxygen which is necessary for their mineralization. When dispersion and diffusion are satisfactory, the discharge of sewage into a large body of water is scarcely, if at all, detectable to the sight.

It is sometimes erroneously assumed that diffusion is everywhere and at all times proceeding rapidly among the liquid particles naturally present in large bodies of water, particularly in such bodies as move under tidal influences, and that to cause sewage to be carried away, it is only necessary to discharge it in not too great quantity. This is a mistake. Some bodies of water should never receive any sewage.

A prompt and general intermixture of sewage and water is often difficult or impossible to accomplish. It is most difficult when the water into which it is emptied has no current or when the current is so slow that there are no eddies or counter currents produced. The eddies and counter currents are necessary for rapid diffusion. It is not enough that the water into which the sewage is discharged should be great in volume, nor that the water should be flowing by a point of discharge at a great velocity. If the velocity is uniform throughout, dispersion and diffusion will not be as satisfactory as it would be if cross currents and eddies existed in it.

56 Ascent of Sewage in Sea Water.—Diffusion between sewage and sea water is more difficult than between sewage and land water by reason of the greater specific gravity of sea water. Each cubic foot of sewage is 1¾ pounds lighter than an equal volume of sea water and, in consequence of this fact, every foot which is discharged beneath the surface may be considered to be urged upward

with a force of about 1¾ pounds. This upward force diminishes as the sewage becomes mixed with the water and is initially less if the harbor water is not as salt as the sea. From the mathematical equation $V^2=2gh$, it is evident that the rate of ascent will vary as the square of the difference in specific gravity, and that the velocity of ascent will be doubled when the buoying force is multiplied four times.

It is, unfortunately, impossible accurately to determine the velocity of ascent of a stream of sewage by means of this or any other formula, but the facts stated are of practical use in considering the best means of causing a prompt and intimate mixture of the sewage and tidal water to take place.

Many experiments have been made by the Metropolitan Sewerage Commission to obtain information concerning the circumstances under which sewage could and could not be made to diffuse in the water of New York harbor. These experiments were carried on in the laboratory, in large aquarium tanks and in the harbor itself. In the latter case, hogsheads and tank steamers loaded with sewage were taken to various parts of the harbor and, after being strongly colored with dye, discharged beneath the surface, and the resulting phenomena noted. In these experiments the harbor water varied in salinity. It usually contained about 75 per cent. of sea water. The current into which the sewage was discharged varied from a little less than 1 foot per second to 3 feet per second. Most of the large scale experiments were carried on near the center of Upper New York bay. Further details of this work are described in the report of the Commission of April, 1910, pages 184-215, but the following facts and opinions derived from these studies are of interest here. When sewage is discharged into sea water, the sewage will rise to the top in a mass unless it is intermixed through the mechanical action of eddies and cross currents. Tending to carry the sewage to the top are gas, grease and light solid particles. The sewage is usually warmer than the water into which it is discharged and this difference in temperature tends to carry the sewage upward.

When sewage is discharged into a mixture of 85 per cent. of land water and 15 per cent. of sea water, it appears to be practically in equilibrium, that is, it neither rises nor falls through the water into which it is discharged.

When sewage is allowed to stand at the top of a perfectly
57 quiet body of water, diffusion occurs at once if the water is land water, but not until 48 hours, if the water is a mixture of equal parts of land water and sea water. When sewage is discharged beneath the surface of a quiet body of water, currents are set up which help to produce an intermixture between the two fluids. The force of these currents varies directly with the velocity of the discharging current and the volume of discharge, and is helpful in bringing about dispersion and diffusion. When sewage is discharged beneath the surface of a quiet body of water of practically the same specific gravity, it does not intermingle immediately with the surrounding water. Some diffusion takes place from the outside edges

of the discharging stream, but intermixture seems to proceed chiefly after the discharging stream has lost its initial velocity. It is obvious from these facts that the velocity is an important factor in the mixing process.

If directed vertically upward from a submerged outfall, a discharging stream of sewage flows toward the surface of the water in a gradually enlarging column. Arrived at the top, the sewage spreads out thinly over the surface. Diffusion gradually takes place downward from this surface. If discharged horizontally from a submerged outfall, the sewage stream at first preserves its integrity for a considerable distance and then, rising upward, spreads out in a thin layer at the top of the water. Diffusion takes place in this case downward from the gradually enlarged column and from the surface layer, as when sewage is directed vertically upward from a submerged outfall.

When sewage is discharged into a quiet body of tidal water consisting of 40 per cent. land water and 60 per cent. sea water, it rises toward the surface irrespective of the direction of the discharge from the orifice, and spreads out upon the surface in a thin layer. The upward motion is not retarded perceptibly when the discharge takes place at a velocity of 1½ feet per second into quiet water.

The shape of the discharging column of sewage is larger and longer when the discharge takes place in a horizontal direction than when the discharge is upward or downward, and for this reason, a horizontal discharge facilitates diffusion. To secure the most prompt and thorough intermixture, the sewage should be discharged in a horizontal direction near the middle and at the bottom of a tidal channel and in a direction perpendicular to the direction of flow of the current.

Three conditions are desirable in order to accomplish satisfactory diffusion:

1. The diameter of the discharging column of sewage should be small.

2. The velocity of the discharging column of sewage should be great.

3. The current into which the sewage is discharged should be rapid.

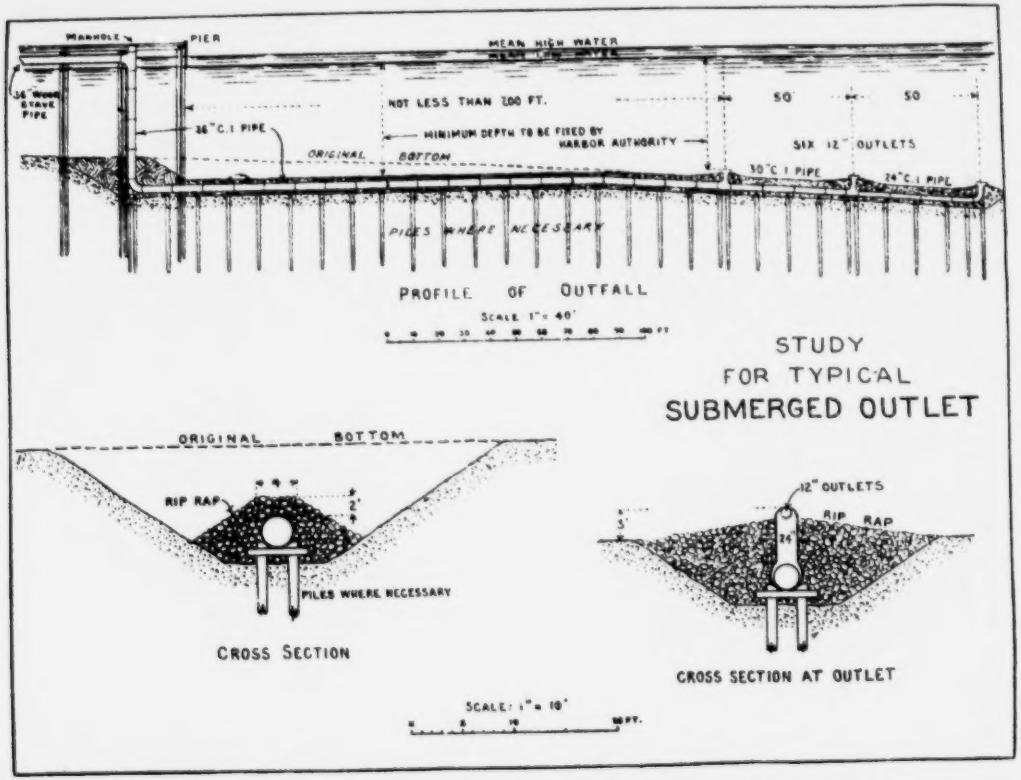
58 Investigations in Boston Harbor.—The water in the vicinity of the Boston, Mass., outlets was analyzed by the Metropolitan Sewerage Commission of New York during the month ending September 18, 1911. The analyses were intended to show the amount of dissolved oxygen in the water, the salinity and temperature being determined at the same time. The examinations covered the inner and outer harbor and there were special studies made of the three main outlets. The total number of analyses was 388. The method employed, the analyst and the floating laboratory were the same as had produced the large amount of information concerning the oxygen in the waters of New York harbor.

The condition of Boston's inner harbor, as measured by the dissolved oxygen was, in the main, very satisfactory, although there

were some places where the circulation of tidal water was insufficient to carry away the sewage which was discharged. The outer harbor, except in the immediate vicinity of the three main sewer outlets, contained an abundance of dissolved oxygen.

The conditions surrounding the Peddocks Island outfall were better than those found at Deer Island or Moon Island. It became apparent that the sewage began to be dispersed and diffused from the moment it left the outfall at Peddocks Island. The shape of the ascending column of sewage was somewhat like a funnel with incurved sides and broad flare. At a distance of 500 feet from the center, there was 7 per cent. of sea water mixed with the sewage at the surface. There was 3 per cent. 10 feet below the surface and 1 per cent. 15 feet below the surface. At 1,000 feet from the center there was no sewage below 10 feet beneath the surface. At 2,000 feet there was no sewage below 2 feet beneath the surface.

The amount of oxygen present varied with the concentration of sewage. At a distance between about 700 feet and 1,700 feet from the center of the sewage field, there was a considerable increase in the exhaustion of oxygen.



Submerged Outlets for Manhattan and Brooklyn.—For the discharge of sewage from Manhattan and Brooklyn it is desirable that submerged outfalls should generally be employed. In some cases they should extend sufficiently far from the outer ends of the piers to obtain the advantages of great depth of water, high velocity of tidal current and remoteness from observation.

The types of construction suitable for carrying the sewage to the bottom of the main tidal channels must differ according to local circumstances, particularly the depth of water and character of the bottom, whether of silt or mud or rock. In the Lower East river the currents are so swift and the bottom so hard and the traffic so great that submerged outfalls can be constructed only with difficulty. On the Hudson river side of Manhattan Island, the
59 & 60 conditions are more favorable and for this area a type of outfall has been designed.

The capacity of the type of outfall which is here outlined for the Hudson river side of Manhattan Island can be increased beyond that mentioned, although the sizes given will be found economical to construct and it may be undesirable to collect more sewage to a single point for disposal than can be discharged through one outfall of this type.

The plan is to carry the sewage through a 36 inch wood stave pipe laid beneath a pier to a point near its outer extremity. The wood stave pipe would be joined at its outer end by a 36 inch cast iron pipe which would be placed vertically and extend to the bottom of the water. At the top a manhole would be provided for easy access for inspection, cleaning and repairs.

At the bottom of this vertical leg the 36 inch cast iron pipe would turn and run out into the tidal channel for a distance of not less than 200 feet from the outer end of the pier. At this distance there would be a short riser of 24 inch pipe, provided with two 12 inch

(Exhibit No 20 2)

PLATE VIII

outlets which would discharge in a direction parallel to the main line of the pipe and perpendicular to the direction of the tidal currents.

From the riser just mentioned, the cast iron pipe, now reduced to 30 inches, would extend 50 feet further from shore to a second riser similar to the first. From this point the cast iron pipe reduced to 24 inches in diameter would extend the final 50 feet to its outer limit, where it would be joined by a third riser to discharge the remaining sewage, as in the first two cases.

The cast iron pipe would, where practicable, be laid in a trench dredged in the bottom. Where the support was poor or uncertain, piles would be driven to carry the pipe. The pipe would be covered with a light filling of rip-rap and the trench filled. The minimum depth at which outfalls of this character should be constructed would have to be fixed by the Harbor Line Board. Apparently there is a depth of water in the Hudson river along the Manhattan shore at practically all points sufficient to permit this form of construction to be adopted. A study for a submerged outfall is shown in Plate VIII, following page 60.

The submerged outfalls would be for the dry weather flow of sewage. Storm water would be overflowed under the piers. The dry weather flow of sewage would generally be carried to the submerged outfalls by pumping.

(Here follows Plate VIII, Exhibit No. 202.)

61

IV.

Opinion of U. S. Engineers on the Proposed Island.

Recognizing that responsibility for the maintenance of a proper depth of water for navigation in the harbor rested with the U. S. War Department and that the island proposed by the commission for the disposal of the sewage of the Lower East river could be constructed only with the permission of that Department, application was made to the Secretary of War requesting the views of the War Department with respect to this subject. The commission's application was referred by the Secretary of War to the Chief of Engineers, U. S. Army, and by him to the New York Harbor Line Board for report.

The New York Harbor Line Board consists of Colonels W. T. Rossell, W. M. Black and S. W. Roessler of the Corps of Engineers, U. S. Army. The island would be in that part of the harbor which is under the special jurisdiction of Col. Roessler, who has had much experience with breakwaters and other structures intended to resist the destructive action of the sea. The Harbor Line Board gave a hearing on the commission's project on March 7, 1913. On that occasion the subject was thoroughly discussed, plans, charts and profiles of the proposed structures being produced.

The opinion of the Harbor Line Board was transmitted to the commission by the War Department on March 22, 1913. It was to the effect that an island in either of the two locations suggested by the commission, one of which is shown on Plate I, following page 48 of Preliminary Report VI of the Metropolitan Sewerage Commission, would not interfere unduly with navigation nor have an unfavorable effect upon the harbor. In this opinion the Chief of Engineers concurred.

The correspondence in full follows:

February 18, 1913.

Hon. Henry L. Stimson, Secretary of War, Washington, D. C.

SIR: In making plans for a sanitary disposal of the sewage of New York City, it has become desirable to consider the practicability of constructing an island near the entrance of New York harbor. The island would be located on one of the shallow, sandy bars which are divided by the Fourteen Foot Channel to the north of Ambrose Channel.

62 The island would be constructed with an enclosing wall of rip-rap and a filling of sand or other solid material, the total area occupied being less than 30 acres. Upon the island would be tanks and other structures in which much of the solid matters of the sewage would be removed to be carried to sea in boats or disposed of in some other acceptable manner, while the clarified effluent would be discharged into the surrounding water through outlets so arranged as to insure its prompt dispersion and disappearance. The sewage, amounting to about 200,000,000 gallons per twenty-four hours, would be brought to the island through a tunnel.

Recognizing the authority which is exercised by the general gov-

ernment over the navigable waters, this commission desires to place its project in sufficient detail before you, to the end that an early determination may be reached as to the permissibility of constructing and using this island in the manner, and for the purpose, stated.

Members of this commission will be pleased to call upon you with reference to the subject in case you visit New York, or they will go to Washington to see you, if preferable. The technical details of this plan can be laid before such army engineer, officer or officers of the New York Harbor Line Board as you may designate.

Your early attention to this subject is requested in order that the result of your consideration may be known in time to be used in a report soon to be issued by this commission.

Respectfully,

GEORGE A. SOPER,
JAMES H. FUERTES,
H. DE B. PARSONS,
CHARLES SOOYSMITH,
LINSLY R. WILLIAMS,
Commissioners.

March 3, 1913.

Mr. George A. Soper, President, Metropolitan Sewerage Commission, 17 Battery Place, New York City.

DEAR SIR: 1. The Harbor Line Board has before it your application of Feb. 18 to the Secretary of War concerning the construction of an artificial island near the entrance to New York harbor, and also a letter of Feb. 19th from Mr. H. de B. Parsons, Consulting Engineer, requesting that this matter be laid before this Board. In order that the Board may be able to come to a [illegible] conclusion in the case, it is requested that you submit more detailed plans and make a definite application for such construction.

63 2. The Board desires to take this matter up at 10 a. m. on March 7th and it is requested that these plans be submitted before this time and that if possible you or your representatives be present to confer with the Board in the matter on that date.

Very respectfully, WILLIAM T. ROSSELL,
Colonel, Corps of Engineers, Senior Member of Board.

March 6, 1913.

Colonel William T. Rossell, Corps of Engineers, New York Harbor Line Board, Army Building, New York City.

DEAR SIR: Your letter of March 3, relating to the proposal of this commission to construct an island near the mouth of New York harbor, has been received.

Application is hereby made for permission to construct and maintain an island for the treatment and disposal of sewage in accordance with the following plan:

The object of constructing the island is to afford opportunity for the treatment and final disposition of a quantity of sewage from the inner harbor sufficient to relieve and protect the inner harbor from its excessive burden of pollution.

The location proposed for the island is in shoal water, preferably

in latitude 40° 32′ 02″ N, longitude 73° 59′ 46″ W, or in latitude 40° 31′ 26″ N, longitude 73° 58′ 21″ W.

In plan, the island would be approximately rectangular except that the seaward side would be rounded. The area at the start would be about 20 acres of filled land and about 10 acres of harbor for the protection of vessels engaged in transporting supplies to the island and taking sludge and other materials away.

The outer face of the island will be a wall of rip-rap composed of large pieces of broken stone carried to the site on boats and laid upon the hard sandy bottom. It is expected that some settlement will at first occur, due to the water cutting sand away from under the stone. The main bulk of the island will be composed of sand supplied from a suction dredge which will take its supply from the bottom of the sea, or earth, ashes and other suitable material.

The height of the island above mean low water will be about 18 feet. The length of the island, when first constructed will be about 1,300 feet and the width 1,000 feet. The side of the rip-rap wall which is exposed to the sea will have a slope of 1 vertical upon 3 horizontal and the two adjoining sides will have an outer slope of about 1 on 2. The rip-rap will be 15 feet across the top and
64 will be surmounted by a concrete parapet wall 4 feet in height. The rip-rap will be from 75 to 122 feet wide on the bottom, according to the location with respect to the sea.

The island will contain a plant of settling tanks in which the sewage will have an opportunity to settle and deposit its solid matters during a period of about two hours. These tanks will be modified Dortmund tank construction, similar to those recently constructed at Toronto, Canada. Provision can be made for treating the sewage, if necessary, with a coagulant before passing it into the tanks.

After treatment, the sewage will be discharged through a number of outlets arranged radially from the island in such position as to bring about the most immediate and perfect dispersion of the sewage practicable. If desirable, it will be feasible to pump sea water and mix it with the sewage before the discharge take place. Such admixture would facilitate the immediate diffusion of the sewage in the sea water; but the active agitation and free movement of the great volume of water in the vicinity of the island will, it is expected, make a preliminary mixture of sea water and sewage by pumping unnecessary.

The material which will settle out of the sewage in the tanks will be carried to sea in vessels and dumped sufficiently far from the land to insure that no trace will reach bathing beaches, inhabited shores or oyster grounds.

Provision will be made for a laboratory and dwelling house for those who will be needed to operate the tanks and other devices for the treatment and discharge of the sewage. It will be feasible to maintain a light on the island for the benefit of navigation, in case this is desirable.

In course of time, it will be necessary to increase the size of the island and it is proposed that this will be done by extending its

length so that the total area covered will be about three times that of the original island, or, approximately, 70 acres.

The quantity of sewage which will be brought to the island at the beginning is estimated at about 203,000,000 gallons per 24 hours during dry weather. During storms, this volume will increase about 100 per cent. This sewage will be collected from those parts of Manhattan and Brooklyn whose drainage is naturally tributary to the Lower East river between the Battery and 28th street, Manhattan. It is proposed to collect the sewage by building intercepting sewers close to the water front to receive the sewage from the existing combined sewers and gather it to a central pumping station to be located near the Brooklyn Navy Yard. A siphon built beneath the East river, will carry the sewage of Manhattan to the Brooklyn side. At the central pumping station the sewage will be pumped through a force main built as a tunnel to the island. The tunnel will be over 20 feet beneath the bottom of the Lower bay and so be free from injury to anchors even in the deepest parts of the channel between the island and the mainland where vessels rarely anchor. The sewage will consist of the ordinary dry weather flow except at periods of rainfall when the storm water from the streets will also be received to the extent of about once the volume of the average hourly production of house sewage.

65 All the sewage which is sent to the island will have been passed through grit chambers and screens with openings not larger than one-half inch. The sewage from Manhattan will be screened before passing to the Brooklyn side. Since it will be relatively fresh, it is estimated that no less than 15 per cent of the suspended matter will be extracted. Grit chambers will be located near the screens and their efficient operation will be insured by the necessity which will exist for removing the readily settleable material from the sewage in order to prevent obstructions in the siphon and interference with the pumps. The Brooklyn sewage will be passed through screens and grit chambers no less effective than those of Manhattan before the sewage is pumped through the force main. It is estimated that the settling basins on the island will remove at least 60 per cent of the suspended matter from the sewage. It is expected that the total effect of the treatment by grit chambers, screens and settling basins will be to remove considerably more than 75 per cent of the suspended matter originally present.

It is believed by this commission that either of the two locations here proposed for the island will be favorable for the sanitary disposal of the sewage and will be free from objection from the standpoint of navigation. Both sites are upon sand reefs where no vessels except fishing craft of lightest draft are likely to pass. The area of the island, even when extended to the dimensions which may ultimately be necessary, will be so small, as compared with the total area of the Lower bay, as not seriously to interfere either with the tidal prism or with the force or direction of the tidal currents flowing in and out of the harbor. The amount of solid matter contained in the sewage when discharged will be slight as compared with the volumes of water in the vicinity of the island and the action of

the waves and currents in this part of the harbor are so active that it seems improbable to this commission that deposits of any serious extent would be formed, even if the sewage was to be discharged in crude condition.

Apart from permission to build the island, which this commission would interpret as expressing a belief that no interference would be caused by the island to navigation, this commission would value the opinion of the Harbor Line Board as to the probable capacity of the island to resist the destructive action of the sea. It is recognized that the Army Engineers posses the qualifications of experts on this subject. If material criticism can be brought against the proposal of this commission for the construction of the island on the scope of structural defect, suggestions looking to a more durable form of construction would be regarded in the light of a public service.

Accompanying this letter is a chart of Lower New York bay, showing the two alternative locations for the proposed island, a profile giving the line of the tunnel through which the sewage would be pumped to the island, a plan of the island and three cross sections of the retaining walls.

Respectfully, GEORGE A. SOPER, *President.*

66 March 22, 1913.

Hon. George A. Soper, President Metropolitan Sewerage Commission, 17 Battery Place, New York City.

SIR: Referring to your letter of the 18th ultimo, submitting, for the views of this Department, a proposition of the Metropolitan Sewerage Commission of New York, as part of a plan for the disposal of the sewage of New York City by the construction of an island in Lower New York bay, I beg to inform you that the New York Harbor Line Board, to which the matter was referred, reports under date of 15th instant, as follows:

"The Board is of the opinion that an artificial island in the Lower bay between Coney Island and Sandy Hook in either one of the two locations shown on the map, and with the dimensions across the direction of the bay and flow of the tide substantially as shown, will not interfere unduly with navigation, nor have an unfavorable effect upon the harbor. Before issuing a formal permit it is suggested that the Sewerage Commission be requested to submit a map showing the approximate position and size of the island it proposes to build at the present time and proposed future enlargement, and the location of the sewers between it and the shore; also such details of the plan of the settling basin or other means for clarifying the sewage as may be necessary to show whether or not such plan will effectually prevent solid matter escaping into the channel in undue amount; also a profile of the proposed sewer showing the depth below low water along its entire route and beyond the crossing of Coney Island Creek."

The Chief of Engineers concurs in the views of the Harbor Line Board, and the map referred to showing dimensions, etc., is transmitted herewith.

Very respectfully, ROBERT SHAW OLIVER,
Assistant Secretary of War.

a COMPLAINANTS' EXHIBIT No. 203. James D. Maher, Commissioner.

NEW YORK CITY, May 19th, 1913.

This certifies that a copy of the within report has been filed in the Mayor's office by the Metropolitan Sewerage Commission.

JAMES MATTHEWS,
Executive Secretary.

Preliminary Reports on the Disposal of New York's Sewage.

VII.

Critical Reports of Dr. Gilbert J. Fowler, of Manchester, England, and Mr. John D. Watson, of Birmingham, England, on the Projects of the Metropolitan Sewerage Commission with Special Reference to the Plans Proposed for the Lower Hudson, Lower East River and Bay Division.*

Metropolitan Sewerage Commission of New York.

George A. Soper, James H. Fuertes, H. de B. Parsons, Charles Sooysmith, Linsly R. Williams, Commissioners.

February, 1913.

1 *Report of the Commission Introducing the Reports of Messrs. Fowler and Watson.*

Honorable William J. Gaynor, Mayor of the City of New York:

SIR: The reports here published represent critical studies by eminent experts who were called upon by the Metropolitan Sewerage Commission in the autumn of 1912, to examine various projects which the commission was considering for the protection of the Harlem and Lower East rivers against excessive pollution by sewage.

Preliminary plans had been prepared by this commission for the disposal of the sewage tributary to these bodies of water, but owing to the radical character of the remedies which seemed to be necessary, and the large sums of money involved, this commission considered it desirable to subject the projects to competent and unprejudiced criticism.

Messrs. Fowler and Watson were requested to come to New York and study the data which had been collected by this commission, remain long enough to become personally acquainted with the situation and to weigh the relative merits of the alternative plans which

*This report is issued in advance of the final report of the Metropolitan Sewerage Commission in order that the contents may be of early service.

had been made to improve the situation. The two experts came to America separately and made their studies independently of one another, although, while still in New York and, later, in England, they met and exchanged opinions.

Dr. Gilbert J. Fowler, who came first, is a chemist. He is a Doctor of Science, Fellow of the Institute of Chemistry, Fellow of the Royal Sanitary Institute of Great Britain and author of numerous reports, papers and contributions to the science and art of sewage purification. The sewage disposal works of Manchester, England, of which he is superintendent, have been developed under his direction until they constitute the largest plant of their kind in the world. These works include screens, settling basins, contact beds, sludge storage reservoirs and steam vessels for transporting the sludge to the open sea.

Mr. John D. Watson, who is a Member of the Institute of Civil Engineers of Great Britain and a Fellow of the Royal Sanitary Institute, is an eminent consulting engineer and expert in sewage disposal. He is in charge of the sewage purification works for Birmingham which are as large and efficient as any of their kind. Originally consisting of farm lands, where the sewage was taken for disposal in the hope of utilizing its manurial properties, these works have been rebuilt by
Mr. Watson in accordance with modern scientific principles
2 and include settling basins, sludge-digesting tanks, supplementary settling basins, percolating filters, screens and sludge-drying beds.

These two reports, which are of similar scope, therefore approach the subject from the separate standpoints of the chemist and the engineer. Each recognizes the necessity of stopping the existing pollution and improving the harbor without loss of time and critically discusses the nature and extent of the works which will be required. In each report the conclusion is reached that a large part of the sewage which is tributary to the Lower East river and Harlem should be collected in large sewers to be constructed near the water front and carried by tunnel to an island to be constructed in the sea at the mouth of the harbor, there to be discharged after enough of the impurities have been removed to insure that no nuisance or injury to health will result. This project was reported upon by the Metropolitan Sewerage Commission under date of January, 1913.

The standard of cleanness proposed by this commission in its report of August, 1912, is approved by Dr. Fowler and Mr. Watson as a code of minimum requirements. Mr. Watson, like some other sanitary experts who have been called upon to advise in regard to this standard, would have the harbor waters kept cleaner than the commission's requirements demand. Dr. Fowler discusses the present pollution in considerable detail and gives much attention to the need of cleanness with respect to these waters. Both experts lay emphasis upon the fact that the pollution has reached large proportions and is rapidly increasing.

The opinion is expressed by both that if the digestive capacity of the harbor for sewage is not to become overloaded to the point of nuisance, it will be necessary to carry a large part of the sewage away

for disposal, it being beyond the range of practicability to purify it near where it is produced.

It is pointed out that sewage works which are capable of effecting a high degree of purification are so likely to produce odors and nuisance from flies that it is desirable to avoid the construction of such works within the city limits as far as possible. For this reason only such comparatively crude and simple processes as employ settling tanks, grit chambers and screens should be considered for installation on the shores of Manhattan Island and Brooklyn. There is no land anywhere within the limits of Greater New York upon which it would be permissible to construct works capable of purifying the sewage tributary to the Lower East river and Harlem by percolating filters, such as Mr. Watson employs at Birmingham, or contact beds like Dr. Fowler uses at Manchester, because of the nuisance which would result.

After discussing other alternatives, Messrs. Fowler and Wat-
3 son arrive at the conclusion that the proper solution of the problem is this commission's proposal to carry the sewage which is naturally tributary to the Lower East river, and eventually that which is tributary to the Harlem, to an island to be built at sea. On this island the sewage would be passed through settling basins and perhaps treated with electrolyzed sea water, in accordance with a method with which the Metropolitan Sewerage Commission has made some experiments. The effluent from the island should be discharged in such a way as to cause the organic matters present to be thoroughly mixed with large quantities of fresh sea water and, consequently, oxidized and rendered permanently harmless and inert by natural agencies.

Neither Dr. Fowler nor Mr. Watson has been dissuaded from endorsing this project on account of its cost. Their opinion is that the money for such sewage works as are necessary for the health, welfare and reputation of the port will be forthcoming, when once their necessity is understood. It is pointed out that other cities, and among them many small places, have spent much more per capita for sewage disposal than would be required here.

Mr. Watson has given considerable attention to the form of administration which is most suited for the construction and maintenance of the necessary main sewers and sewage disposal works and his experience as Chief Engineer of the Birmingham, Tame and Rea District Drainage Board, which represents a number of municipalities in addition to Birmingham, gives him special qualifications to deal with this subject. He recommends that a commission be created which shall have charge of the building and maintenance of such sewage disposal works as are necessary for New York and in this suggestion, Dr. Fowler, with a knowledge of the details of the recommendation, concurs.

The reports of Messrs. Fowler and Watson contain so much that is of value from scientific and practical standpoints and their statements seem so capable of aiding the public to understand New York's large

and complicated problem of sewage disposal that their two reports are herewith published in full.

Respectfully submitted,

METROPOLITAN SEWERAGE COMMISSION OF NEW YORK.

5 *Report of Gilbert J. Fowler, D. Sc.*

To the President and Members of the Metropolitan Sewerage Commission of New York.

GENTLEMEN: In accordance with the request of the Metropolitan Sewerage Commission, conveyed to me by the President, Dr. George A. Soper, in a letter dated September 27th, 1912, I arrived in New York on the 10th November, 1912, and remained, with brief absences in Boston, till Wednesday the 27th November.

During this time the following inspections were made:

By water: 1. Upper bay,
2. East river to Long Island sound,
3. Round Manhattan Island,
4. Through the Narrows to Far Rockaway and into Jamaica bay.

By land: 5. To Gravesend bay, Coney Island, Sheepshead bay and Canarsie, visiting disposal works at Sheepshead bay, Paerdegat basin and 26th Ward,
6. To Newtown creek, returning to Manhattan, recrossing the Lower East river below Hell Gate and skirting the edge of the Upper East river including Steinway, Flushing bay, Whitestone and Douglaston.

I also visited Boston, and through the courtesy of the Massachusetts Board of Health, was able to inspect the three types of sea outfall there. The same day I visited the Lawrence experimental station and discussed the work being done with the chief chemist. On these various expeditions numerous photos were taken of important points such as some of the larger sewer outlets, proposed places of discharge &c.

A good deal of time was spent in the laboratory of the commission overlooking and discussing experiments on the possibilities of electrolysed sea water as a precipitating and sterilising agent for the sewage. I also had much conversation and discussion with reference to the data accumulated by the commission, and was shown numerous data hitherto unpublished, especially in reference to the possibilities of complete nitrification taking place in mixtures of sea water and fresh water.

6 The President was good enough to demonstrate for me the method used by the commission in their fundamentally important work on the dissolved oxygen in New York harbor. The method is rapid and accurate and well suited to the conditions of investigation. I have carefully studied both before and since my visit to New York the extensive and valuable reports issued by the commission as well as the report by Major Black and Prof. Phelps.

Immediate Conclusions.

I was impressed at the outset by the vastness and complexity of the problem to be dealt with. London may have a larger present population but the conditions for discharge are infinitely simpler.

In addition to the rapidly increasing population directly or indirectly discharging its sewage into the harbor, the problem is complicated by the outstanding facts, viz:—(1) the growing scarcity and value of unbuilt upon land in the vicinity of the harbor, (2) the comparatively small amount of water available for flushing out the bay, this being limited practically to the flow of the Hudson. The thickly populated districts abutting on the Harlem river and the Lower East river discharge into waters which ebb and flow with the tide, but suffer very little actual change, little or no excess water passing out of the bay or into it at each tide.

As a consequence, the conditions to be met with in the Harlem and Lower East rivers call for immediate action. Not only is the bottom polluted, but the water, even in favorably situated portions of these rivers, is deficient in oxygen, in the majority of cases to nearly 50 per cent. In many places there are local nuisances already, and floating fæcal matter, paper, &c., are in frequent evidence. What the conditions are likely to be when the surrounding districts, increasing as they are now doing, to say the population of 1940, it is not pleasant to conjecture. It is evident that something will have to be done here and done at once. When the volume of sewage to be dealt with, over 350 million gallons per day at the present time, and more than 700 million gallons by 1940, is considered it is evident that for this section of the work alone considerable expenditure will have to be faced.*

In view of the very large expenditure involved, it is difficult to exaggerate the importance of adequate preliminary studies and the work of the commission throughout appears to me to be a model of the way in which such investigations should be carried out.

7 The conditions are so complicated, owing to the diversified character of the land and water areas constituting New York harbor and its surroundings, that endeavors to reproduce them artificially, as is often done in research work, are likely to be only partially successful. The method of thoroughly studying the actual state of things obtaining in the bay and other waters in the vicinity under all conditions of season, tide and weather, as has been done by the commission, seems the only possible one, and the work has been done with masterly completeness. No question necessary for the formation of a right judgment on the questions which should be settled at this time appears to have been left unstudied by the commission.

The citizens of New York may rest assured that the large sum of money they will be called upon to pay for the protection of their harbor will not be asked for except as the result of opinions formed

* Report Metropolitan Sewerage Commission of New York, August, 1912, p. 28.

after years of study much more complete than is generally given to such a subject. Every year, however, the conditions now existing must necessarily grow worse and, while in the case of a growing science like that of sewage disposal it is well to hasten slowly, yet through the labors of the commission there will exist no justification on the score of imperfectly known data for postponing certain most necessary works.

Principles Governing Consideration of the Problem.

The conditions which must be realized if the constituents of sewage are to be rendered inoffensive or finally mineralised are essentially the same whether the disposal be by irrigation upon land, filtration through artificial biological filters, or dilution with fresh or salt water. The process is in all cases one of oxidation, i. e., practically speaking, combustion, and if it is to be conducted without nuisance, enough oxygen must be present at all stages of the process to prevent the formation of evil smelling products.

It is perfectly legitimate to use the oxygen dissolved either in sea or river water in order to oxidise sewage. Under proper conditions of discharge, complete transformation and mineralisation of the sewage matters can be effected in this way with less nuisance than often accompanies treatment on filters or on land.

The question of the margin of safety which should be allowed if nuisance is to be avoided has been the subject of reports by a number of well-known experts to the Metropolitan Sewage Commission * and all of these reports agreed that under no circumstances should the dissolved oxygen in the harbor be allowed to sink to below 50 per cent. of saturation. In this opinion I concur. It will, however, be most unwise to be content with a margin simply sufficient to barely eliminate nuisance.

Two main considerations govern the situation from the point of view of public policy; these may be described as considerations of Health and Welfare.

Health.—There are obvious ways in which public health may be directly affected by the filthy conditions of parts of the harbor or even by the apparently innocuous discharge of sewage or sewage effluent.

It is not a pleasant sight to see numbers of floating fæces wasihng in and about piers where food supplies are landed from lighters some of which have a low free board. Gulls and flies may also quite possibly be carriers of infectious material under such conditions.

The question of oysters is of more direct importance. Even if sewage or sewage effluent is actually sterilised, the growth of oysters near an outfall is always a possible source of danger, and while it is quite easy to exaggerate this, yet it can never be in accordance with right sanitation for an article of food to be thus contaminated.

The pollution of bathing sites has been dealt with at length by

* Report Metropolitan Sewerage Commission of New York, August, 1912, pp. 69-164.

the commission.* The conditions which at present exist are unsatisfactory in the extreme.

The carrying of polluted driftwood daily into the homes of the poor in the neighborhood of the water front does not tend to raise the standard of cleanliness in such homes and should be prevented rather by stopping pollution than by forbidding what is in itself a reasonable and thrifty proceeding.

But even more important than the direct and obvious ways in which the public health is affected by the polluted condition of the harbor waters, is the practically unconscious lowering of that sense of decency and cleanliness of living which must be maintained if the efforts of social reformers are to have any serious result.

Crowds of people from the poorer quarters of New York throng the recreation piers and pleasure drives on the water front. If it is obvious to them that those in authority, who have the power, are yet unconcerned to abate uncleanly surroundings, the already not inconsiderable effort required to maintain a decent spot of home life in a mean environment, will be rendered even harder to achieve.

Welfare.—The second consideration, viz., that of welfare, as it has been termed, is perhaps less obvious, but is most important when expensive works, the use of which is partly for future generations, have to be considered.

9 A study of the history of sanitation, such for example, as was possible in the historical section at the International Hygiene Exhibition in Dresden in 1911, will show that, up to comparatively recent times, conditions were tolerated which to us would seem unspeakable. Yet even now the standard of requirement is constantly rising. One may, indeed, frankly say that the modern American bathroom both in its fitting and the frequency with which it is to be found is a distinct advance upon what is common even in England. Such a bathroom, however, increases the difficulty of the sewage problem, and in looking forward to the future, similar advances in public requirements must always be reckoned with. The idealism manifested in such great buildings as the Pennsylvania Railroad station and the Metropolitan Museum of Art and the parks and playgrounds of the city will find its further development in a demand for brightness and beauty in the surrounding water spaces. Nor is such idealism unrelated to mere purely economic prosperity. The true solution of any problem is true at all points, sanitary, æsthetic, ethical and economic.

Apart from the question of affecting the vitality, and consequent wage earning capacity of the people, the reputation of a port is a very essential factor in its commercial prosperity. The condition of the Clyde and of the Manchester ship canal was for many years a by-word. The great sewerage and sewage disposal works at Glasgow carried out at a total cost of over £2,000,000 for 800,000 people have been the means of rehabilitating the reputation of the Clyde

* Report Metropolitan Sewerage Commission of New York, April 30, 1910, pp. 486-497.

and adding to the amenities of life, pleasure trips being now possible from the Bromielaw to the Firth of Clyde.

The large amount of money spent on sewage works in the watershed of the Mersey and Irwell is, apart from the increasing expenditure of Manchester itself, slowly but steadily improving the water of the Manchester ship canal.

At one time the stench from the polluted Thames in hot weather rendered the committee rooms in the houses of parliament in London uninhabitable. By the removal of the sewage to treatment works and outfalls lower down the river this nuisance has been abolished, and London is now one of the healthiest and best drained cities in the world.

In the case of the three cities above referred to, their works were carried out under urgent pressure of obvious and almost intolerable nuisances from the polluted streams. New York should deal with her problem before such acute conditions arise.

The foregoing general view of the situation clearly indicates that any scheme which is decided upon must not block the commercial avenues of the future. It must be so designed as to be capable of expansion as the needs of the city increase.

10 Possible Methods of Dealing with Sewage.—The various possible methods which are available for dealing with sewage on the large scale may be broadly divided into:—

1. Direct discharge into water.
2. Discharge after screening.
3. " " sedimentation.
4. " " chemical treatment.
5. " " filtration in some form,
6. " " combination of processes.

The proportional amount of impurities removed by these processes depends on numerous factors, e. g., the freshness and strength of the sewage. Thus, screening will remove a much greater proportional amount from very fresh sewage than from sewage which has been mixed and churned up for many miles in a trunk sewer. Chemical treatment is more economical with strong sewage than with weak, and therefore is of less advantage with American sewage than with European.

Very roughly, it may perhaps be assumed that under the conditions existing in New York, of the nuisance-producing solid material in sewage capable of producing deposits of sludge, the following percentages can be removed by the respective processes:—

Screening and grit chambers	3-6 per cent.
Short sedimentation	50 "
Chemical treatment	75 "

None of these processes seriously affects matters in solution. Filtration affects not only the finely divided colloidal matter still present after the foregoing processes but also oxidises substances in solution.

Which of these methods can be used at any of the various proposed points of outfall in New York harbor is to be determined by local conditions. What these conditions are is considered in the next section.

The Present Polluted Condition of the Harbor.

Broadly, the waters of that part of New York harbor which lies in New York State may be considered separately as follows:—

The Hudson river,
The Upper bay,
The East river and the Harlem river.
Jamaica bay.

11 Of these, the Hudson river contains the most dissolved oxygen, this amounting to over 90 per cent. of saturation in the centre of the river in the northern part of Manhattan and diminishing to 60 per cent. near the Battery. The Hudson river supplies practically the only water available for flushing the harbor. All along the edge of the Hudson among the piers objectionable conditions exist.

The Upper Bay.—All the pollutions from the waters entering the harbor at certain states of the tide, as well as those resulting from direct sewer discharges are mixed by tidal currents in the Upper bay and a proportion of the solid matters is doubtless deposited there during the ebb and flow of the tide. This is evidenced by the polluted character of the dredgings from the bottom of the Upper bay at nearly every point of observation. Considerable deposit of sludge has been found south of Governor's Island.

The general appearance of the waters of the Upper bay is by no means attractive. Large fields of sleek, or oily film, are frequent and, more objectionable, are masses of floating debris in which large quantities of fæcal matter are often entangled. The Gowanus canal is but little better than an open sewer, there being an insufficient circulation of water to dilute the large volumes of sewage discharged into it.

The East River and the Harlem River.—It is on these rivers, especially in the Lower East river and the Harlem that, as already stated, conditions exist which call for urgent remedy.

Large sewers discharge from the thickly populated districts on both sides of these waterways and there is little or no net tidal discharge. As a result, the bottom of the upper East river as far as Throg's Neck at the entrance to Long Island Sound is foul, and in the Lower East river, in places unaffected by the ebb and flow of the tidal currents, foul deposits occur.

In the Lower East river from the Williamsburg Bridge to Hell Gate the dissolved oxygen present, especially in the summer months is not much more than 50 per cent. of saturation.* In some parts

* In the summer of 1912 some samples of water from the Lower East river, near the Brooklyn Bridge, were found to contain 43 per cent. of oxygen.

of the Harlem river it is less than this. There are portions of the Harlem river already approaching the condition of the Manchester ship canal, while Newtown creek has practically reached that condition. In the vicinity of Wallabout basin there is a large sewer outlet which produces a small lake of sewage in its vicinity, which is most objectionable.

There is no doubt that if the sewage which now enters crude into the Lower East river and the Harlem river could be taken up
12 and dealt with in a satisfactory manner, very great benefit would accrue not only to these waterways but also to the Upper bay and Upper East river into which much of the sewage eventually finds it way.

Jamaica Bay.—The characteristic feature of Jamaica bay and its vicinity is the growing summer population of numerous pleasure resorts, such as Bergen Beach, Arverne, Edgemere, Canarsie and Rockaway. The conditions which I saw in November were, therefore, hardly typical. Effluents from treatment works at Sheepshead bay and the 26th Ward, though obviously imperfectly purified were not the cause of serious visible pollution.

In view of the increasing population and of the schemes of harbor development which are being considered, it will be necessary before very long comprehensively to deal with the sewage which at present discharges into the bay.

The question of oyster pollution must here, also, be dealt with and it should be clearly understood that ordinary methods of treating sewage give little protection from a bacteriological point of view, while processes of sterilization may easily produce a false sense of security. It would seem best for oysters not to be taken near densely populated centres, as under such circumstances the chances of pollution, apart from the sewage which is discharged from actual sewage outfalls are considerable.

Proposed Remedies.

Sewage Tributary to the Lower East River and Harlem River.—As already emphasized, the first point of attack in dealing with the problem of purification of New York harbor is the Lower East river and the Harlem river, and I have given my most careful consideration to this part of the commission's work.

After much study the commission have concluded, and I think rightly, that the only point where large quantities of sewage can be treated in this neighborhood is at Ward's Island. It is possible to pick up the sewage which at present discharges into the Harlem river and also that which is turned out of the large sewer at Hunt's Point and bring it all to Ward's Island where it can be treated in settling tanks and the heavier sludge removed.

Some 124 million gallons daily would be thus dealt with at once, and over 400 million by 1940,* and would be discharged into the

*Preliminary Repoort IV, of the Metropolitan Sewerage Commission on the Disposal of New York's Sewage, July, 1912.

swift tidal currents at Hell Gate where the best possible conditions exist for mixing.

13 Sedimentation, however, leaves a large proportion of potential solids still present as well as all the impurities in solution. Treatment by chemicals instead of by plain sedimentation would remove a further proportion of the suspended impurities, but the treatment in this way of such large volumes of sewage as may be taken there involves numerous difficulties and greatly increased cost, which would weigh heavily against the advantages obtained. Further purification, by filtration, at Ward's Island is impracticable, and also not to be recommended so near large centres of population owing to the possibilities of ærial nuisance and fly trouble on large areas of filters.

It becomes matter, therefore, for careful consideration how far the concentration of the sewage to one point and discharge into the local waters after elimination of the grosser solids would really relieve the situation. It is to this point that most careful thought has been given and the bearing of all the available data studied under every aspect.

Owing to the fact that the waters rushing through Hell Gate only pass back and forth with the tide and do not really get away to the ocean, it is evident that whatever sewage is discharged at Hell Gate is largely dependent for its oxidation on the oxygen in the water with which it mixes in one tide. The Lower East river is, however, highly polluted and the discharged effluent will therefore not get much help from it. The situation, in fact, is only improved by the elimination of the grosser solids from the sewage of the Harlem district. If the situation is to be radically improved, the conclusion seems inevitable that some sewage must be removed from the Lower East river.

From figures supplied me by the commission, I calculate that if the sewage of the Harlem territory is collected and passed through settlement tanks on Ward's Island, and if the sewage of those parts of Brooklyn and Queens which would ordinarily discharge into the Lower East river be removed altogether, there will then be a dilution representing 1 of raw sewage to 200 of water in the Lower East river at mean low tide.

This is a considerable improvement on present conditions, representing a removal from the Harlem and Upper and Lower East rivers, together with about 50 per cent. of the total sewage which at present pollutes them.

It is, however, from the Manhattan waterfront that the greatest proportional volume of sewage enters the Lower East river. It exceeds the volume discharged into this division of the harbor from Brooklyn and Queens by about 50 per cent. The further conclusion, therefore, is forced upon one that a really satisfactory solution of the problem must involve the removal of this sewage also. Indeed a study of the statistics show that if this is not done, the Lower East river in 1940, will revert to a condition even worse than exists to-day.

14 Disposal at Sea of that Part of the Sewage of Brooklyn, Queens and Manhattan Which Would Ordinarily Discharge into the Lower East River.—The conditions discussed in the foregoing section show clearly that the sewage from these districts will have to be removed from the Lower East river if the situation is to be properly dealt with.

From the researches of the commission there would appear to be three possible outlets for this sewage.

The first possibility is to take it to Barren Island and there treat it in tanks, followed, possibly, by some form of filtration and discharge it near the entrance to Jamaica bay. At the same point would be collected the sewage now very imperfectly dealt with at the various sewage works discharging into the creeks on the northern shore of Jamaica bay. The point of outlet would be at the entrance to Jamaica bay.

Barren Island itself is, however, little more than half a mile from the large summer population on the Rockaway peninsula, and if, as is not at all improbable in hot summer weather, some amount of smell should arise from the filters, it is not far enough away to prevent a nuisance to these people. Moreover, the point at which the effluent would discharge is not half a mile from thronged bathing beaches. There are therefore these grave objections to an outlet near Barren Island.

A second alternative proposition has been considered, viz:—the removal of the sewage to the west side of Staten Island, with the erection of purification works there. Apart from engineering difficulties which I am informed exist in carrying so much sewage across the very deep channel of the Narrows, the conditions of final discharge would render purification by biological filters necessary, and similar objections would again arise in regard to nuisance from these as have been pointed out in regard to the Barren Island project.

Under these circumstances a third alternative has been suggested which seems to me to have much to recommend it. This proposition is to build an artificial island well out in the Atlantic, nearly three miles from the shore of Coney Island, and there construct settling tanks, and discharge the effluent after settlement of the bulk of the suspended solids, into deep water, with proper engineering precautions to ensure thorough mixing of the effluent with the seawater.

After inspection of the Boston sea outfalls I am clearly of the opinion that no point of outlet should be less than 40 feet in depth, and that the discharge should be continuous so as to minimize the quantity sent out in any interval of time.

15 The sludge deposited in the tanks could be readily taken well out to sea in tank steamers of the pattern used in Europe, as at Glasgow, Manchester, Salford and London.

I understand that the island can be made without difficulty from the spoil and debris from excavations in New York city at present taken out to sea, or from sand pumped from the bottom of the sea,

I understand, also, that it will be possible to increase the number and length of the outfall pipes as more and more sewage is coupled up to the island, so that the effluent will always be well distributed in the sea water. The operations can be carried on without causing nuisance to any one, the conditions for sea disposal of sludge in tank steamers are very simple. The scheme is capable of indefinite expansion as more sewage is taken up, as the size of the island itself can be increased as extensions to the works are required.

Many matters rather of detail remain for further consideration in regard to the methods of treatment employed both at what may be termed "Atlantic" Island and Ward's Island. The design of the settlement tanks to be employed is a question of importance. A form of tank is to be preferred which would expose as little water surface as possible and also allow automatic removal of the sludge by the pressure of the supernatant water. A modified form of two-story tank would seem well suited to this purpose.

The sludge produced by the thorough fermentation which takes place in the so-called Emscher tanks, while greatly reduced in bulk and offensiveness, would offer some difficulties in carrying to sea, owing to its being saturated with gas. It is possible that judicious admixture with salt water would obviate this difficulty. In any event the disposal of sludge is not the least difficult part of the problem. There will not be more, for a long time at any rate, than is at present handled at the London outfalls, and the conditions of sea disposal are simpler in the case of New York.

For reasons indicated when referring to works on Ward's Island, I do not recommend treatment by chemical precipitants. I think, however, that very careful study deserves to be given to the practicability of adding a small dose of chlorine to the effluent, e. g., by the addition of a certain volume of electrolysed sea-water. This would serve the double purpose of deodorising what may be a somewhat malodorous effluent after its long travel through the sewers, and a further important advantage would lie in preventing an immediate call upon the dissolved oxygen in the sea at the point of discharge, and thus giving time for more thorough mixing and aeration to take place.

Some Further Problems.—There are many matters of importance, subsidiary to the large scheme outlined above which call for brief mention.

16 A system of screens and catchpits has been designed for Manhattan Island, which could afterwards be used for screening storm water, overflowing from the main sewers later to be built. It is in my view important that this should be carried out, in order that even after large sums have been spent on main sewers and outfall works, there should not be public disappointment, when visible pollution is seen to be present after every shower of rain. Before such refuse is removed, however, means must be at hand for its rapid incineration in suitably placed destructors.

The scheme of outfalls and outfall works designed by the commission for the districts abutting on the Upper East river seems to

me to be adequate, at any rate, for many years. The outlets are all in deep water and the conditions resemble those of the Clyde summer resorts or English lakes, where the sewage of a fairly large population is disposed of without serious difficulty.

Time did not permit me to study the problems connected with Staten Island actually on the spot. From a perusal of the commission's report on the disposal of the sewage of the Richmond Division there would not appear to be any special difficulty in dealing with the situation as far as regards the responsibility of New York City.

In the Arthur Kill and Kill van Kull we are approaching the problems of New Jersey. I have not been called upon to express an opinion on matters which are a subject of litigation. One may, however, safely say that a resolute handling by New York City of her own problems is likely to facilitate an equitable conclusion.

Summary and Conclusions.

After careful consideration of the situation as it has been placed before me I am of opinion that the sewage of the Harlem district should be collected and treated in sedimentation tanks on Ward's Island.

This will relieve the immediate and pressing situation on the Harlem river. It will, however, do little or nothing to improve the Lower East river.

It is of equal importance, therefore, that the scheme be pressed forward of driving a main sewer southwards through Brooklyn to an artificial island well out from shore in the Atlantic ocean, where tanks could be built for settling out the heavier suspended matters and removing them to sea.

Into this main sewer would first be discharged that part of the sewage of Brooklyn and Manhattan which at present passes in a crude state into the Lower East river. Later, more of the sewage of Manhattan should be coupled up to this sewer, the outlets at the artificial island being extended with each large increment of sewage.

17 Next, the sewage from the Jamaica Bay Division might be brought to the island and finally, if thought desirable, the sewage which, during all this time had received treatment at Ward's Island.

By this sequence of procedure the experience gained at Ward's Island would be of value in designing the final disposal at the "Atlantic Island," and at any rate a large proportion of the money expended in tanks, &c., at Ward's Island will have been redeemed before the works are abandoned. The expenditure in sewers in the Harlem district will be for permanent works alone.

The order of carrying out the various needful works and the time over which the construction should extend would all be matters within the control of the permanent commission suggested by my colleague, Mr. Watson, with whose views on this aspect of the question I heartily concur.

This same central board or commission would care for the other

less immediately pressing, but still highly important, problems referred to in the later paragraphs of the foregoing report.

The above represents in broad outline the lines upon which, in my opinion, the City of New York should proceed in its endeavour to obtain a harbor worthy of itself.

It must again be emphasized that no time should be lost in setting about the actual carrying out of the scheme. It must of necessity take a number of years to complete, and equally of necessity the condition of the harbor waters must become progressively worse if nothing is done, and will indeed probably be worse before the first instalment of the work is completed.

I am, however, confident that the citizens of New York will show the same determination and largeness of outlook already manifested in their great water supply projects, their colossal railway undertakings, and magnificent bridges and public institutions, in this further effort after social well-being, and will build the works necessary to cleanse the harbor and make it worthy in every respect of its great position as the Gateway of the West.

Respectfully submitted,

GILBERT J. FOWLER.

Manchester, February 10, 1913.

18 *Report of John D. Watson, M. Inst. C. E.*

To the President and Members of the Metropolitan Sewerage Commission of New York.

GENTLEMEN: I have given the problem of the sewerage and the sewage disposal of your great city my close and careful consideration during the past two months.

The fortnight which I spent in the city in the end of November and beginning of December gave point and animation to the study which was not otherwise possible, and I take this opportunity of thanking you for the ready access you gave me to all your documents, plans, and analytical figures, and for the facilities with which you provided me in the inspection of every part of the area which I thought it essential to visit. Allow me also to record my appreciation of the exhaustive preliminary investigations which you have made. These far exceed anything which I have hitherto had experience of, and the fact of your having printed them renders unnecessary reference to details which otherwise would have had to be given in this report.

The Polluted Condition of the Harbor.

If there were any prospect of limits being set to the bounds of New York, if there were any signs that sufficient accommodation had already been made for the shipping of the port, or if the waters of the harbor were so foul that the citizens had ceased to regard them as valuable for other than utilitarian purposes, the disposal of the sewage—vast as the volume of that is—would be comparatively easy.

But it is quite otherwise. The city is more than the capital of a country; it is the greatest city of a continent. The harbor is the gateway to the United States, and the noble rivers which find a ready outlet into it form, with the harbor proper, a port which affords at all stages of the tide no halting welcome to vessels of the greatest burden.

When I first had the pleasure of seeing the Hudson between Albany and New York, I was greatly impressed by its grandeur and its purity; when I motored along its left bank from Riverside Park toward the city boundary at Yonkers in brilliant sunshine, I thought it the Queen of Rivers, and I cannot believe that the average citizen would willingly allow it to become visibly polluted with sewage, yet the facts to which I shall refer will prove that it is necessary to take steps now to guard against such a contingency in the immediate future.

19 Visible Pollution.—The numerous analyses of the harbor waters made by your own officers, supported by men of such eminence as Professor Phelps, Dr. Adeney and Dr. Fowler, and the clear evidence of pollution which I have witnessed, lead me to the opinion that continuance of the present unhampered license to pollute can only lead to disaster. When it can be shown that even now the condition of the harbor in summer is obviously unclean, it is only a question of time when an ever-increasing population discharging an incremental amount of sewage and trade waste into what must be practically a stationary volume of harbor water will convert into a nuisance what should be one of the brightest and best of the city's possession.

One of my first actions in prosecuting this study was to investigate the condition of the harbor water, and even in the end of November I found at several places a slight smell of sewage. In ferrying across the river between 92nd Street and Astoria I observed innumerable particles of paper and even pieces of excrementitious matter in the water. Sea gulls indicated where the public sewers debouched directly into the river.

In many places in the East, the Harlem and the Hudson rivers, the Gowanus and Wallabout bays, visible evidence of the presence of sewage was only too apparent. Near the Battery I saw food which had just been unloaded from a boat that was moored in what looked more like sewage than clean water. At another place (Gowanus canal) I witnessed the ebullition of gas apparently arising from septicized sewage sludge. Large flows of greasy sleek and debris were to be seen at frequent intervals. Open ends of sewers spewing their filthy contents into the rivers are of much too frequent occurrence.

One and all demonstrate the same lesson that the time has arrived when a standard of cleanness should be set and maintained. If such conditions were offensive in November and December, it is obvious that they must be worse in the hot seasons of the year. Of course offensiveness to sight and smell do not necessarily constitute a nuisance which is dangerous to health, but as no self-respecting com-

munity would tolerate streets that were rarely scavenged because no injury to health could be traced to them, no port of the first rank should permit excrement paper, straw and grease to flow to and fro on the surface of the chief highway into the city because it could not be proved that a human being had died as the result.

The Proper Standard of Cleanness.—The standard of cleanness which you suggest, and which I heartily approve, should be reasonably but strictly enforced.* Liquid pollution, although less obtrusive, is not less in need of prevention, and it is in the interest of the community to see that any recognized standard which may be decided upon should be conscientiously adhered to. What the standard should be is a question which you have already submitted to a number of well known experts, and they have all united in saying that the dissolved oxygen in the harbor water should not be allowed to fall below 50 per cent. or 60 per cent. of the saturation limit. Colonel Black and Professor Phelps suggested that it should not be allowed to fall below 70 per cent. saturation, and this figure is more in accordance with my own view; indeed I go further and say that an even higher standard is feasible if the project recommended later in this report is approved and given effect to.

The result of 289 samples tested by you for dissolved oxygen in the summer of 1911 show clearly the polluted state of some parts of the harbor. Taking 100 per cent. as the saturation point, or the normal condition of clean water, the following comparison of average figures speak volumes:—

---

* Report Metropolitan Sewerage Commission of New York, August, 1912, page 70.

20 **Standard of Cleanness.**

1. Garbage, offal or solid matter recognizable as of sewage origin shall not be visible in any of the harbor waters.

2. Marked discoloration or turbidity, due to sewage or trade wastes, effervescence, oily sleek, odor or deposits, shall not occur except perhaps in the immediate vicinity of sewer outfalls, and then only to such an extent and in such places as may be permitted by the authority having jurisdiction over the sanitary condition of the harbor.

3. The discharge of sewage shall not materially contribute to the formation of deposits injurious to navigation.

4. Except in the immediate vicinity of docks and piers and sewer outfalls, the dissolved oxygen in the water shall not fall below 3.0 cubic centimeters per litre of water.† Near docks and piers there should always be sufficient oxygen in the water to prevent nuisance from odors.

5. The quality of the water at points suitable for bathing and oyster culture should conform substantially as to bacterial purity to a drinking water standard. It is not practicable to maintain so high a standard in any part of the harbor north of the Narrows or in the Arthur Kill. In the Lower bay and elsewhere, bathing and the taking of shellfish cannot be considered free from danger of disease within a mile of a sewer outfall.

---

† With 60 per cent. of sea water and 40 per cent. of land water and at the extreme summer temperature of 80 degrees F., 3.0 cubic centimeters of oxygen per litre corresponds to 58 per cent. of saturation.

Lower New York bay	98	per cent
Long Island Sound near Throgs Neck	96	"
Hudson river, a few miles above Manhattan Island	81	"
Narrows	73	"
Upper East river	71	"
Kill van Kull	66	"
Hudson river to north of Manhattan Island	64	"
21 Upper New York bay	63	per cent
Lower East river	55	"
Newark bay	54	"
Harlem river	42	"

Average figures in such a study do not quite suffice, for as the strength of a chain is the weakest link, so the lowest figures obtained (30 per cent at the lower end of the Harlem in July, 1911) indicate the danger conditions which sanitarians would strain every nerve to avert.†

The Increasing Discharge of Sewage.—When one remembers that the population of New York was only 2,500,000 in 1890, and that in 1905 it was 4,000,000, a careful estimate of its probable growth in the future is essential to arrive at a wise judgment in the matter of sewage disposal.

Estimates have been made by several authorities, including Freeman who said the population in 1940 would be..... 7,652,000
and Laidlaw who said it would be..... 8,662,829
The New York Telephone Company's estimate is..... 8,747,000
and the Board of Water Supply's estimate is..... 9,258,600

The average of these suggest a probable population of the city in 1940 of 8,580,107, a figure which proximates to your own estimate of 9,000,000, which be it remembered is based on the Census figure of 1910, and on this account is more likely to be accurate.

The prospective population which should be reckoned, however, is not 9,000,000 but 12,000,000, the population of the metropolitan area. The question as to what extent the harbor is likely to be burdened with impurities in 1940, assuming that nothing is done in the interval, depends on population more than anything else, and whether that population is located north, south, east or west of the harbor makes no difference. Artificial boundaries, therefore (state or other), are obviously not so important to the issue as watershed, and far fetched as it may appear to be at first sight the manner of disposing of the sewage of the City of Albany and every other populous place built and to be built on the banks of the Hudson will materially affect the problem under consideration. This will be apparent if it is conceded that the recuperative influence of the har-

† The percentage of oxygen fell still lower in 1912. The average for the year: Hudson river off Pier A, 55 per cent.; Narrows, 70 per cent.; Kill van Kull, 65 per cent.; Upper New York bay, 64 per cent.; Lower East river, 47 per cent.

bor depends very largely upon the purity or otherwise of the Hudson as it enters New York City.

22 The act of assimilation can be carried on only in the presence of oxygen, and it is therefore essential to conserve that oxygen as much as possible.

The table which I have quoted to show the relative state of purity at various specified places as measured by percentage of loss of oxygen is eloquent condemnation of the existing system, a condemnation which is only partially mitigated by the naturally and wonderfully even admixture of the harbor water as shown by the voluminous observations you have made.

In studying this question the fact that the volume of sewage must increase constantly has to be set in juxtaposition with the fact that the clean water from whence the oxygen is derived must remain very much the same in all time. Nor should the floating population as represented by the trade of the harbor be ignored. This is certainly a difficult problem, and I fear it will be impossible to exclude sewage from this source altogether; it is the more important, therefore, that the authorities deal effectively with the sewage from the stationary population which is under control.

Cleanness, a Commercial Necessity.—On the day I arrived in New York the newspapers referred to a remarkable speech by the Mayor on the subject of the growth of imports and exports at several harbors of the United States. The occasion for this speech was the 144th anniversary of the organization of the Chamber of Commerce, and it was shown that the increase of trade at New York was far and away greater than at any other port in the country.

Since 1898 the increase at the port of New York was									111	per cent.
"	"	"	"	"	"	"	"	Philadelphia "	75	per cent.
"	"	"	"	"	"	"	"	Boston "	17	per cent.
"	"	"	decrease	"	"	"	"	Baltimore "	7	per cent.

All the facts and considerations of the case lead me to the conclusion that the community must bestir itself if it would retain for its harbor the good name which is now associated with it. Let the cases of Marseilles and Glasgow, be a warning. Many years ago the Clyde became so foul that even poor trippers declined to board pleasure steamers nearer to the Broomielaw than Greenock several miles down the river. Since that time large sums of money have been spent on sewage disposal works, but the bad reputation justly associated with the name of the Glasgow harbor years ago will not be got rid of for many years to come. Every port has a duty to every other port, which if faithfully observed, would inaugurate a state of things that would go far to lessen the duties of port, sanitary and quarantine officers.

23 Discussion of the Metropolitan Sewerage Commission's Four Schemes for the Purification of the Harbor.

What then is the most practicable, the most hygienic and the most permanently economical scheme to adopt? I have studied the vari-

ous schemes put forward in the admirable reports which you have sent to the Mayor of the City since September, 1911.*

* Metropolitan Sewerage Commission's Preliminary Reports on the Disposal of New York's Sewage, I to V inclusive.

Although the schemes enumerated in your reports may not have exhausted every phase of what you term the art of sewage purification, yet in my view you have considered every method applicable to New York which can be regarded as reasonably practicable.

Scheme 1 refers to the application of sewage to land. (Broad irrigation and intermittent filtration.)

Scheme 2 refers to filtration of sewage through biological filters (bacteria beds).

Scheme 3 refers to treatment of sewage by a variety of methods at various points of outfall, each case being adapted to its special circumstances, and the ultimate disposal of partially purified liquid into the nearest water course.

Scheme 4 refers to the conveyance of a large part of the sewage out to the Atlantic ocean with the minimum of treatment.

Scheme 1.

Application of the Sewage to Land.

The popularity of irrigation as a means of purifying sewage is on the wane, chiefly owing to the extensive area required and the unsuitability of the land available.

The Berlin farm, which is the largest in Europe, continues to do good work. The largest farm in England was at Birmingham, but some years ago when land could no longer be obtained for less than three times its agricultural value, the authorities abandoned irrigation in favor of the intensive method of purification on bacteria beds. The largest farm in France is at Paris, and there also the authorities contemplate a change of method whenever it is necessary to increase the purification plant.

Where all the conditions are favorable, irrigation is undoubtedly successful as a vehicle of purification, and one which gener-
24 ally yields consistently good effluents, but in New York the farm would be so colossal in extent that the conditions would not be invariably favorable. The available land is, I fear, limited to Long Island, the area required would exceed 150 square miles. It would necessarily vary in its adaptability for the purpose, and although the standard of purification need not be exceptionally high in view of the large volume of water into which it would ultimately be discharged, it would still be necessary to limit the volume of sewage to 10,000 or 12,000 gallons per acre, unless a great expenditure for under drainage were undertaken.

Sanitary Objections.—A great area of land lying between Amityville and Quogue overlies one of the sources of the city's present water supply, and its use for sewage purification would be a potential source of plague which no one would care to risk.

The mere saturation of 150 square miles of land with sewage would be a menace to the inhabitants obliged to reside in the district, and would be sure to produce mal-odors during certain states of the atmosphere, which would be highly objectionable, even if they did not markedly influence the health statistics of the district.

I disapprove of this method of purifying New York sewage on grounds quite apart from cost; nevertheless, it is important to note that it is the most costly of the schemes brought forward, and would probably amount to $180,000,000; this, too, assumes that land could be acquired for about $500 per acre—a somewhat sanguine estimate.

Scheme 2.

Oxidation in Bacteria Beds.

The epoch-making experiments of the Massachusetts State Board of Health have led to the adoption of what has been called the intensive method of purification. By this, biological filters are made to take the place of land, and in your case would probably purify 140 times as much sewage as the same area of land under irrigation. It is a method which is almost invariably adopted in modern works which are located some distance from sea, lake or river.

To carry the whole or the major portion of the New York sewage to Barren Island and then treat it on bacterial filters would be costly, and could only be justified if it could be shown that a specially good effluent is essential at the point of discharge.

As the oyster beds will probably depreciate in value as the population of the district increases, it would not be wise on this account alone to incur the expense of this operation, more particularly as it is now admitted on all hands that the passage of sewage through a biological filter does not necessarily deprive it of pathogenic organisms, and in order to protect the oysters from the attack of a stray typhoid bacillus, it would in this case be necessary to sterilize before 1940 a quantity of sewage equal to about 700,000,000 gallons.

Danger of Nuisance.—Perhaps Barren Island is the very best site available for placing an installation of percolating filters, but it would appear as if Jamaica bay were on the eve of great developments, and that Barren Island would not for long be the isolated place it now is. I regard it as of the utmost importance to establish sewage purification works where they are not likely to become a nuisance, and I have grave doubts about the wisdom of placing so vast an area as 1,000 acres of bacteria beds so near to an industrial centre as they would be on Barren Island. In contemplating such a scheme there is a factor which should be taken into account, and that is the after effects of the evaporation of so much foul liquid as there must necessarily be from such an area of filters.

In 1911, when the summer weather in England was warmer than usual, there were complaints of smell nuisance at Henley, where the sewage is of about the same strength as the average American sewage, and where it is distributed over rectangular percolating beds by

mechanical distributors moving backwards and forwards. Complaints were also made by residents near the Birmingham works, where the sewage is sprayed over the beds by fixed nozzles.

The chief lesson to be learned from the 1911 experience is that an increase of flies is to be looked for in the neighborhood of bacteria beds in hot weather, and that objectional smell adjacent to them is more pronounced during prolonged hot weather than at other times, e. g., seasons like the average English summer, when the temperature rarely exceeds 65 Fahr. in the shade. But a much more serious drawback to a great area of bacteria beds during spells of prolonged hot weather is the formation of vaporous "clouds," due to the evaporation of sewage. These clouds appear to form over the beds in quiet weather. They rise to some distance above the earth, and at sundown, when the earth begins to cool, they return not alone as refreshing dew, but with offensive odor. If this occurred only in the vicinity of the bacteria beds, where the land is generally less valuable than at some distance, it would not be so serious in its consequences, but it generally occurs at some distance from the bacteria beds, the direction and distance depending upon the tendency and the velocity of the wind.

Cost.—Of course, it is only the mal-odorous element in sewage that makes this phenomenon noticeable; evaporation from clean water would act precisely in a similar manner, but it would manifest itself in welcome dew on the grass. This led me to adopt at Bir-
26 mingham the use of hypochlorite of calcium with excellent results, but the cost would be a serious matter where 700,000,000 gallons had to be treated each day; indeed, the bare probability of hypochlorite of either calcium or sodium (and the latter is even more effective) having to be used frequently, would be sufficient in itself to retard the adoption of a scheme which would be many times as large as anything now in existence. It is obvious that climate is of paramount importance.

The initial cost of 1,000 acres of biological filters to deal with 700,000,000 gallons of sewage, would be not less than $140,000,000, apart from maintenance charges. Altogether, I agree that the commission would not be justified in espousing this scheme as the best available for New York.

Scheme 3.

Local Treatment Works and Outfalls.

It is probably not far from the truth to say that the only purification of organic matter known to nature is an oxidising one, which is brought about indirectly by the agency of bacteria, but whether the vehicle by which the process is brought to fruition is the irrigation farm, the biological filter or dilution with large volumes of clean water, the "combustion" process is practically the same.

To protect the harbor from pollution, it is neither essential to confine the purifying process to one method, nor to one locality, but whether it is expedient or wise to construct dozens of sewage purifica-

tion plants in and around New York is an entirely different matter. Sewage from the various districts delineated on the plans could be sufficiently treated to admit of being discharged in the adjacent waters without creating a nuisance, but in some cases the treatment would have to be very circumscribed, and a greater burden would be placed upon the assimilating powers of the waters than they ought to be called upon to bear.

Essential Details.—It is unnecessary for me to refer in detail to the various outfalls that would be required under this scheme. Suffice it is to say that I have examined many of the suggested sites, with the invariable result that they all appear to me to have been chosen with great judgment and engineering skill. It is more than probable, however, that if Scheme 3 finds most favor, the sites shown on the plans, and referred to in your reports, may have to be altered when negotiations for the purchase of those sites are begun: this will be found to be specially true in the case of the nineteen outfalls on Manhattan Island.

Under this scheme it would be necessary to lay sewers towards an outfall which would terminate in the deepest water available in the vicinity, where it would be dispersed by a complete sy-
27 stem of moderate sized outlets so placed as to enter the stream transversely to the flow, and in sufficient number to encourage equal diffusion. Each outfall should be protected by grit chambers and settling basins in duplicate: the former should be provided with every appliance requisite to remove solids of large size, road grit, rags, etc.

Disposal of the Sludge.—The basins should be built so as to induce the sludge arrested by mechanical or chemical precipitation (as may be found best under circumstances which vary considerably at different outfalls) to collect at, say, the apex of an inverted cone or pyramid, and the sludge collected should be pumped daily into steamboats built for the purpose and removed well out to sea. This system of getting rid of sludge is well suited to a scheme which would have all its sludge tanks within easy reach of navigable water.

In my view the sludge should be removed daily so as to obviate smell nuisance. The only alternative would be to septicize the sludge in Emscher tanks, but this would mean large and deep tanks which would be incompatible with the conditions obtaining at some of the outfalls, particularly those in Manhattan, where the sludge tanks would perforce be placed in the streets abutting on the bulkhead and shore lines. The experience of the engineers at London, Glasgow and Manchester puts at rest any doubt as to the practicability of removing unseptic ized sludge by steamboat, but there is nothing equally convincing to show that if it were in a state of active fermentation it could be so easily removed and so quickly lost to view when dropped into the ocean.

Only Lin ited Treatment Practicable at Wards Island.—If such a scheme as this were to be car-ied out, its weakness would probably become apparent first at Wards Island, where 302,000,000 gallons

of sewage will have to be treated daily in 1940. The reasons I have given against the establishment of a great area of filter beds at Barren Island are even more potent when applied to Wards Island, so that either mechanical or chemical precipitation would in the present state of knowledge have to be resorted to, and neither process is efficient enough to warrant me in suggesting that such a volume of effluent could be discharged into the East river without unduly drawing upon the oxygen of the harbor water.

One of the leading factors in considering the Wards Island problem is the fact that the river, so called, is without a continuous flow of fresh water towards the sea; any sewage effluent, therefore, would have to rely upon admixture with the water of a tide in order to obtain the necessary supply of oxygen to obviate putrefaction, and considering the volume available for this purpose, I am doubtful whether the results would be acceptable at all seasons of the
28 year. Of course the sedimentation process including screening and sludge removal to sea, or that process plus the addition of a coagulant to help mechanical precipitation, do not exhaust the great sources of power in nature, and it is quite possible that we may before many years are over realize the practicability of electrolysed sea water. Your laboratory experiments stimulate me with hope, but I cannot in the present state of my knowledge recommend them as a practical solution of the problem.

Under this scheme there would be many outlets, all of which would require to be equipped with screens, grit chambers, tanks, and some kind of treatment works, before the effluent could be discharged and left for the nearest water to complete its purification by assimilation.

Scheme 4.

Conveyance of a Large Part of the Sewage to Sea.

The distinctive feature of this scheme is the provision of subterranean channels, or great sewers, into which each part of the municipality embraced within a prescribed area would have the indisputable right to discharge sewage and trades wastes without let or hindrance, knowing that the sewage would be conveyed right out to the Atlantic ocean. Nothing in the nature of treatment beyond arresting solids that would otherwise obstruct the pumps would be undertaken en route.

One important feature of this scheme would be the formation of an island in the sea about three miles south of Coney Island. The formation of such an island is by no means unprecedented, but the idea of forming one some miles from land for the sole purpose of treating sewage is a novelty in the history of sewage purification.

Scheme 4 involves pumping the sewage, screening it, arresting a proportion of the suspended solids in sedimentation tanks to be constructed on the island, and thereafter leading it by a series of pipes into deep water to secure effectual diffusion.

Having the sewage tanks on the island would obviate the usual troublesome claims for compensation in respect of depreciation of

value of adjacent property. The island could be extended almost indefinitely as occasion for extension arose. Its position would be the best possible from which the superintendent of the works might observe the ebb and flow of the tide, and regulate the emptying of the sedimentation tanks.

29 The Treatment Necessary.—The question of the extent to which sedimentation should be carried is one which will gradually settle itself. I do not think it will be necessary to effect settlement until after the first section of the work has been in operation for some time, but as section after section is completed it will be found necessary to arrest the solids in tanks, made with the view of concentrating the sludge at the bottom of either conical or pyramidal pockets placed at an elevation to induce the sludge to flow by gravitation.

The precise site of the proposed island will require careful consideration, but that shown on your plan appears to be feasible. Excepting rip-rap for the external formation, nearly all the material for making it can be readily and cheaply obtained chiefly from (1) debris or spoil from building sites which at present is dumped into the ocean; (2) spoils from the tunnels and terminating shaft, and (3) sand pumped from the adjacent sand banks.

The Progressive Steps in this Scheme.—The first step to be taken if this scheme is entertained is to collect sewage from those parts of Manhattan and Brooklyn which border on the East river, convey it by tunnel to a central pumping station at Wallabout, near the Navy Yard, and lift it to another pumping station at Sheepshead bay, whence it would be conveyed to the projected island for disposal.

The population of the districts to be served at first by this instalment, and the dry weather flow of sewage pertaining thereto, are as follows:

District.	Population, 1915.	Sewage, Gallons per day.
Manhattan	680,000	99,000,000
Brooklyn	732,000	104,000,000
Total	1,412,000	203,000,000

The Wallabout pumping station would lift 133,000,000 gallons coming from the north, 18 feet in height, and 70,000,000 gallons from the south, 33 feet in height, and the Sheepshead bay station 203,000,000 gallons about 38 feet in height.

This instalment could be executed for about $18,000,000, which would entail for interest (at 4½% for 50 years) together with maintenance charges, an annual payment of $1,500,000, but I do not recommend you to limit the size of the tunnel to a carrying ca-

30 pacity of 400,000,000 gallons, or about twice the dry weather flow, as I believe the second instalment of the scheme should be undertaken soon after the completion of the first.

The second instalment, I apprehend, would be to couple up the intercepting sewer which would serve the Jamaica Bay Division, shown on the plan accompanying your report to the Mayor, dated November, 1911.

The third instalment of the work should bring the sewage of the Upper East river and Harlem Division into the system, and the fourth would take in Richmond and as much of New Jersey as may be determined.

In my opinion all the intercepting sewers should be capable of conveying not less than twice the dry weather flow before storm water is shed into the nearest watercourse; this would correspond favorably with the English practice of conveying six times the dry weather flow,* or rather less than 200 gallons per head per day.

Need of a Permanent Sewage Disposal Commission.

Of the four projects thus briefly outlined as possible schemes for adoption, I have a decided preference for Scheme 4. I admit that Scheme 3 is feasible, but it lacks finality and possesses features which should be avoided when possible, e. g. the numerous outfalls and the drawbacks attaching to them in the eyes of the general public, their not invariably suitable locations, and their inevitable increase in number as the population increases. What influences me most in favor of Scheme 4 is the conviction that where it is possible to remove the bulk of the sewage of New York entirely away from its source to the ocean it should be so removed, although the cost may be somewhat higher than it would be under a project like Scheme 3.

In a great city where such public services as water supply, sewerage and sewage disposal are indispensable, and where several self-governing municipalities benefit by the common service, it is essential in the interests of good and economical administration that there should be a permanent commission, with jurisdiction over the whole area. Such a general commission from its very constitution is enabled to deal with questions more comprehensively than local boards, commissions, departments or bureaus can do. Probably an example of what I mean may be found by reference to the endeavor to improve the insanitary conditions of the Gowanus canal, where a local sewer bureau tried to remedy a nuisance by conveying a stagnant,
31 putrid liquid from one locality to another in the same neighborhood. No doubt the bureau did the only thing available to them at the time, but they were obviously restricted in their outlook, and were forced by circumstances to mitigate rather than remedy the evil, whereas if it had been possible for them to order the polluted waters of the canal to be conveyed beyond the municipal boundaries to the ocean, the evil would have been effectively remedied. A municipal engineer's work is often unfairly criticised because the effects of being hemmed in by surrounding boroughs is not adequately appreciated. Administrative questions, like sewerage, are not invariably united, but here they should be under one commission or board, and it is with the object of devising a workable scheme for keeping the harbor free from solid as well as liquid impurities that I suggest the formation of a commission to be entrusted with the duty

* For comparison between English and American sewage, See Preliminary Report VI, of the Metropolitan Sewerage Commission of New York, January, 1913.

of making and keeping pure (or reasonably pure) the national waters.

Proper Functions of a Permanent Commission.—The constitution of such a commission would have to be carefully framed by those who are well versed in existing statutes and inter-state law, but I venture to suggest one or two points which should be carefully embodied in the constitution.

The whole responsibility for maintaining clean waters within the prescribed area should rest upon the commission, and they should have all necessary power to enforce their regulations.

The commission should be responsible for the design of all intercepting sewers, pumping stations, tanks, outfalls, &c., essential for the construction of a complete installation of sewerage and sewage disposal works. The board should also be made responsible for the construction of these works, and for their subsequent maintenance.

Each borough or municipality must have the same right to connect to an intercepting sewer or sewers that they now have to discharge sewage into harbor, river or watercourse.

The commission should be charged with the duty of seeing that pollution, which must be inevitable until the intercepting sewers or subterranean tunnels are all built and connected to the ocean outfall, does not increase, even although it should be necessary to construct temporary works for the purpose.

The joint board or commission should have ample power to decide whether an intercepting sewer or any other work is required, and to allocate the cost of construction to the users. It should also have power to regulate by bye-laws, or otherwise, everything which pertains to the keeping clean of the harbors, rivers, canals or watercourses within the area for which it is responsible. If it is
32 usual to give such commissions rating, borrowing or financial powers, the board should be so empowered.

In recommending the adoption of Scheme 4 it is not to be assumed that I advocate its complete execution at once. If I have succeeded in presenting the whole project correctly, it will be apparent to all that the dominating factor is and must continue to be the condition of what I have called the national waters. As it stands at present, the putrefactive liquid entering them increases daily; their power of oxidising foul liquid is practically stationary, and as every sewer is diverted to the Atlantic ocean by being coupled up to the system under scheme 4, their condition will improve. I do, however, advocate progressive, consistent advancement until the completion of the scheme be attained, which I hope will be not later than 1925.

Necessity for Immediate Action.

I cannot say too distinctly that there is need for immediate action. The nature and extent of the tunnel work bars haste and precludes all chance of redeeming lost opportunities; therefore no opportunities should be lost.

Generally, I am in sympathy with the plans you have prepared; particularly do I espouse what you call Project I as the first step to

be taken. There should however be a comprehensive plan matured if possible in conjunction with the engineers of the several sewer bureaus, which will indicate how every link of the complete scheme will be caught up in regular progressive stages. This is the more important as there might be more or less prolonged intervals between each successive stage.

It will probably cost not less than $100,000,000 to complete Scheme 4, undoubtedly the largest sum ever contemplated for such a purpose, but no scheme has hitherto been designed for the service of 12,000,000 people. Many small towns have spent more per capita than this estimate implies, and frequently all they gained was the removal of a liquid which possessed potential elements of plague. The citizens by approving the conveyance of all the sewage to the Atlantic will gain that and more, for they will at once purify their harbor and rivers, which never will cease to be the most priceless and most striking physical characteristic of New York.

Comparison with European Undertakings.—If one were to attempt a comparison between the cost of the sewerage systems of European capitals, and what is now proposed for New York, the great disparity between the quantities of potable water used by the inhabitants of cities of the Eastern and Western Hemispheres
33 would arrest attention. The world has been startled by the magnitude of your water schemes. Any European city would have regarded 114 gallons per capita as an extravagent allowance, yet this—which is equal to a daily supply of 500,000,000 gallons—is what is now obtained from the Croton works alone, but rather than curtail that supply, or do anything which might be interpreted to favor a limited use of water for public health purposes, the authorities determined to carry out a gigantic scheme to obtain another 500,000,000 gallons of water per day, this time from the Catskill mountains. The magnitude of the undertaking, and the aggregate cost of bringing in 1,000,000,000 gallons per day will place the New York water supply in a category by itself when a history of the world's great water works comes to be written.

The consumption of water has a direct relationship to a city's sewerage system as regards cost, and it is incumbent upon an engineer in recommending a scheme to satisfy himself that it is not only sound as an engineering proposition, but that it is financially possible. The facts I have brought to your recollection go a long way to show that a scheme of sewage disposal which will ultimately cost $100,000,000 and involve an annual outlay of $5,000,000 for the benefit of 12,000,000 people is not disproportionate to the requirements of the city. But I have not relied alone upon the example of the water works in coming to this decision. The numerous public schools, seats of learning, public institutions, colossal buildings, wide streets, stupendous bridges of unparalleled width, not to speak of railroad, canal and private enterprise, the most recent examples of which may be found in the Pennsylvania and Grand Central stations, which between them have cost not less than $300,000,000, all direct one's attention to indisputable evidence of prosperity and progress, and to what is of even more importance, the attitude of mind which

shows that the people have a profound faith in the future greatness of their marvellous city.

It is quite unnecessary to caution you that all estimates of cost, so far as they have been prepared by me, must be regarded as of a tentative character, and should be accepted cautiously until complete surveys, detailed plans and sections are made, and schedules of quantities drawn up—nevertheless they seem to me to be quite ample for the work contemplated.

I am, gentlemen, your obedient servant,

JOHN D. WATSON.

Birmingham, 31st January, 1913.

a COMPLAINANTS' EXHIBIT No. 204. James D. Mabee, Commissioner.

Report of Observations of Sewage Disposal Works in Hamburg, Dresden, and Frankfurt, Germany, by Samuel A. Greeley, Sanitary Engineer, September, 1911.

1 **Hamburg.**

August 30th and 31st—September 1st.

Description.—Hamburg is a city of about one million inhabitants in Germany, on the River Elbe. The river divides the town into a larger northern section of about 850,000 people, and a smaller southern section of about 150,000 people. Near the center of the northern district is a large lake or basin, called the Alster; and there are several small streams and canals throughout the city. The southern section is chiefly a manufacturing and shipping center, and is all cut up with slips, harbors and docks. The city is a large shipping center and there is a continuous passage of ships of all kinds back and forth on the river. The whole city is sewered on the combined system, and there are numerous overflows for storm water at various points throughout the city, on the Alster and the smaller streams and canals. These overflows are arranged so that no discharge takes place directly into the water courses until the normal dry weather flow has been diluted with rain water in the proportions indicated in the following table for the various classes of water courses:

Volumes of Dry-weather Flow and Rain Water in the Combined Sewage at Time of Overflow.

Kind of water course.	Volume of dry weather flow.	Volume of rain water.
Elbe River	1	1
Lower Alster	1	3-1/2
Upper Alster	1	5
Small streams & canals	1	10

2 This information was given to me by Herr Brunotte, engineer in charge of sewage disposal. Previous to the time of my visit and while I was in Hamburg, these storm overflows had not been used for at least six or seven weeks.

The sewage of the northern district is all conducted to one main point of discharge into the Elbe river. The sewers leading to this point of discharge are large, smoothly built, well ventilated, and have good slopes, so that the sewage reaches the point of discharge in a fresh condition, without much odor. Herr Brunotte told me that the minimum velocity of flow in the system was 0.6 meters (1.97 ft.) per second, but that this minimum was confined to a few small

sewers and that in the main trunk sewers the velocity of flow was about 1.0 meters (3.28 ft.) per second. He estimated that the time of flow for most of the sewage coming to the northern district point of discharge was from two to four hours, depending upon the volume of sewage flowing in the sewers.

The sewage from the southern district will eventually be concentrated at one point of discharge. At the present time, the sewage from only about one-third of the population of this district is so concentrated, the remainder flowing directly into the Elbe through various slips and canals.

With regard to the preliminary treatment of trades wastes, there are certain rules, which Herr Brunotte summarized as follows:

(1) Factories must first neutralize their waste liquors.

(2) Oil, fat, etc., must be held back by a scum board.

(3) Asbestos works and some other special works must have settling basins.

3 Herr Brunotte told me that these rules were not enforced to affect over 25% of the trades waste; and in talking with Herr Helmke (an assistant engineer who went to the disposal works with me), I gathered that this statement was rather optimistic than otherwise.

The Elbe river, as it flows through Hamburg, is a tidal stream. (See accompanying tables of high and low tide at Hamburg, Appendix H.) the water being yellow-colored and turbid, with a fine "mucky" sort of suspended matter. Above the town it is used for the city water supply and is not strongly colored or turbid, but requires filtration to make it a clear, safe drinking water. The intensity of the tide is about 3 meters (9.8 ft.), but the stage of the water at Hamburg varies with the wind, being highest after a long continued west wind which piles the water up stream. I asked everywhere for some data relative to the Elbe watershed above Hamburg, but could find none. Herr Brunotte quoted to me the average flow of the Elbe at Hamburg as being 1125 cbm. per second (25,677,324,000 gal. per 24 hrs.), with a minimum of 150 cbm. per second (3,423,643,200 gal. per 24 hrs.), to be expected once every twenty or thirty years. Herr Brunotte's authority for this statement was a book entitled

"Hamburg in Naturwissenschaftlicher und Medizinischer Beziehung."

Nº 2

At the time of my visit, the quantity of water flowing in the Elbe must have been very low, because this summer has been one of the driest in Germany for many years. I was unable to secure accurate data on this point, but was told that by writing to the Strom and Hafen Bau Abteilung, Dahlman Str., Hamburg, in an official way, the data could be secured. However, I found at Dresden that the Elbe was at its lowest stage this summer, and throughout my travels everyone spoke of the extreme drought in Germany. Herr Brunotte stated that the filtered Elbe water was not unusually hard and was used for many boilers without preliminary treatment. The immense number of ships and tugs passing continuously back and forth on the Elbe keep the surface water churned up so that it is always choppy and there is little opportunity to observe sleek on the surface.

The Disposal Works.—Both northern and southern districts are equipped with disposal works. These consist of (1) coarse bar screens at the end of the main sewer; (2) small grit chambers, and (3) revolving mechanical screens of the belt type.

The old plant, serving the northern district, is located on the river front in a very busy, thickly built up section of the city. The environment is undoubtedly critical. (See photographs Nos. 1 and 2.) Within about four blocks is the seaman's school and the entrance to the new tunnel under the river. (See map of Hamburg, marked Appendix IV.)

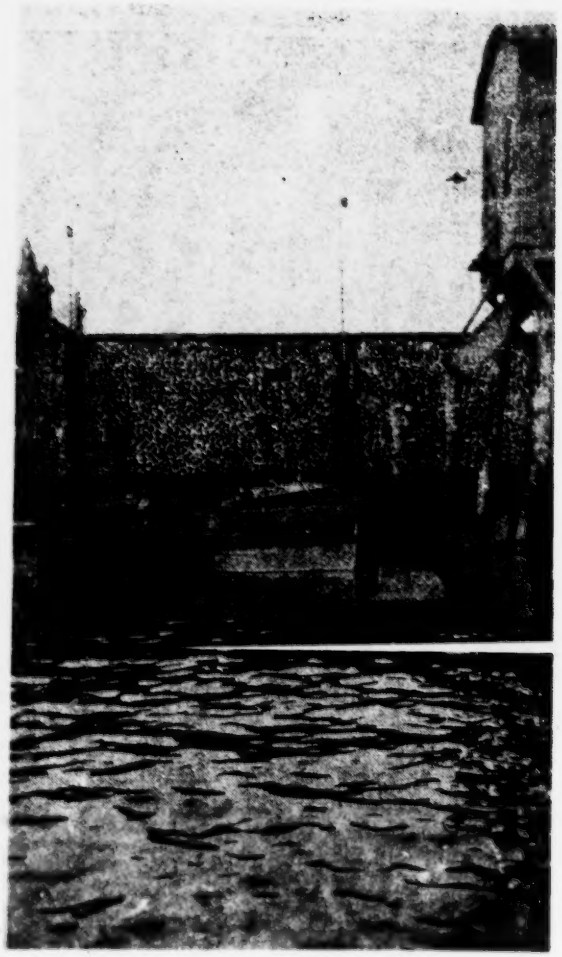
(Here follow photos marked Nos. 1 and 2.)

5 This plant has one grit chamber, containing two screens. The bars of these screens are spaced 15 millimeters (0.59 inches) in the clear, and the screens are each 3.3 meters (10.8 ft.) wide. The screens travel at the rate of about 2 meters (6.56 ft.) per minute, and have only one speed of operation. They operate only at low tide because at high tide the river water is higher than the sewer water. There is a period of from 1 to 5 hours, averaging over 1 hour, when there is no discharge and the sewage is allowed to back up into the sewers. The river is highest when a heavy west wind drives the sea water up stream, and this reaches a maximum when it is combined with a heavy rain. Under these conditions, which I was told happened during the spring of 1911, the period of discharge lasts only for about one hour. (See descriptive illustrated pamphlets of Hamburg's sewers and screening plants—marked Appendix III A and B.)

The average quantity of sewage flowing through this plant is 190,000 cbm. (50,192,300 gals.) per 24 hours. It flows through the grit chamber at a velocity varying from 0.8 (2.62 ft.) to 1.2 meters (3.94 ft.) per second.

The grit chamber is cleaned two or three times a week, the cleanings amounting to from 12 (15.7 cu. yds.) to 16 cbms. (20.9 cu. yds.) daily. The screens, which are cleaned continuously during operation, remove from 10 (13.0 cu. yds.) to 50 cbms. (65.4 cu. yds.) daily, the average removal being 20 cbms (26.1 cu. yds.) per day of wet screenings. The sludge and screenings are dumped into covered steel barges which are towed to the dumping grounds, several miles below the city.

6 After the sewage passes through the screens, there are five discharge pipes through which it may pass into the river. Ordinarily only three of these are used, the other two, which extend only to the water's edge, being used during times of storm flow only. The other three pipes extend into the river 70 meters (229.6 ft.), 100 meters (328.0 ft.) and 133 meters (436.2 ft.) from shore respectively, and all are turned up 90° at the end and discharge at the bottom of the river.



The new plant is located at the end of the Kaiser Wilhelmshafen, and is attractively built of red brick, with well kept up grounds. It is in the heart of a busy shipping neighborhood, in the close proximity of many commercial buildings. (See map of Hamburg, marked Appendix IV.)

The plant consists of two grit chambers, each fitted with two screens; and there are pumps to lift the screened sewage into the river. At the present time the pumps are not connected, and the effluent from the works discharges about midway between high and low tide and at the shore just south of the Reiherstrasse Bruecke.

The grit chamber and screens are very similar to those at the old plant. The important differences are, (1) that the bars of the screen are spaced only 10 millimeters (0.39 inches) in the clear; (2) that the velocity of the sewage striking the screens is less, and (3) that the screens travel more slowly.

The plant is operating below capacity, only about 6,000 cbms.

(1,585,020 gals.) daily of sewage being handled. The grit
7 chamber is cleaned once a week, when about 60 cbms. (78.5 cu. yds.) of sludge are removed.

Work done—Aug. 30.—In the morning I called on Herr Brunotte and talked with him about a half-hour. I returned to Herr Brunotte's office at 1:30 P. M. and met Ing. Helmke, who took me to the new plant and from there by boat to the old plant. This trip took the whole afternoon.

Aug. 31.—About 9:30 A. M. I reached the old plant, to observe the conditions while there was no discharge of sewage. Then I went in a launch down the river, to see where the sludge was handled and, coming back, took samples of Elbe water for observation. This took all day.

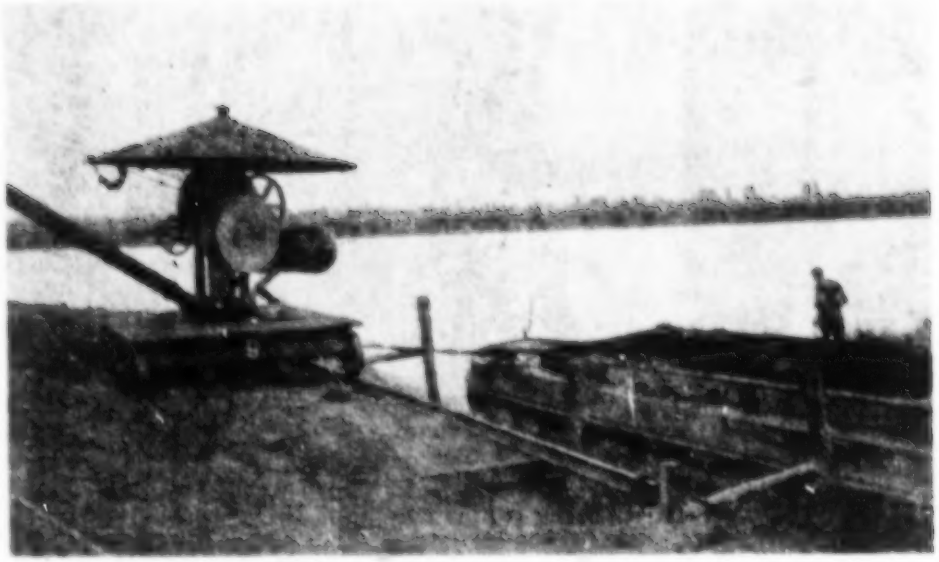
Sept. 1.—In the morning I called on Herr Brunotte again and talked with him for about one hour. Later I called on Ing. Heinrich Luhr, who is now in the water bureau, and questioned him with reference to the water supply.

General conditions during visit.—The summer of 1911 in Germany has been a very dry one, one of the driest in twenty or thirty years. Previous to my visit, it had not rained for six or seven weeks, and during my visit there were only one or two short, light showers, that left no apparent effect on the pavements and affected the sewage flow but little. For the rest, the weather was clear, with a fresh breeze blowing most of the time.

8 Visits made Aug. 30.—Ing. Helmke and I left Herr Brunotte's office about 1:30 P. M. and proceeded by trolley, ferry and on foot to the new screening plant on the south side of the Elbe. The general appearance of the plant, as we approached it, was attractive and no sewage odor was noticeable until we had entered the grounds. They were trying out some sprinkling filters which smelled a little, but the strongest odor noticeable was from the tower used to discharge the sludge and screenings into the tank boat. (See photograph No. 3.) We passed this on our way to the pump house and screen room. It could not have been called objectionable, but the wind was blowing the odor away from me.

(Here follow photos marked No. 3, No. 4 and No. 5, pages 9 and 10.)

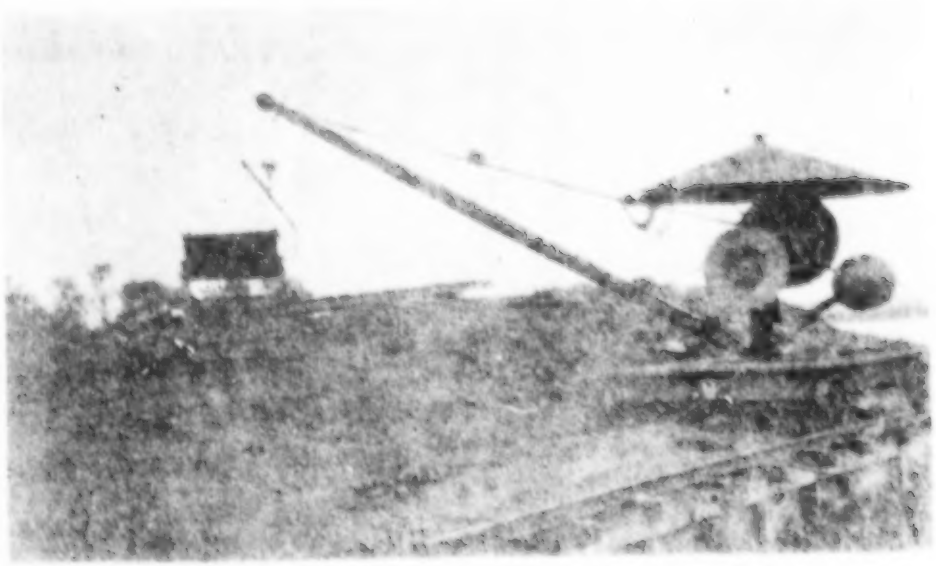
11 Inside the screen house there were evidences that the plant was not having sufficient sewage delivered to it. The screens were not operating and the sewage was flowing through very listlessly. The sewage was black and greasy in appearance and there was evidently much oil in it. They started the screens for me and also lifted a bucket full of sludge for me. This action liberated a lot of gas bubbles in the sludge, and they bubbled up through the heavy liquid but did not smell strongly. After observing the screens and grit chamber, we went to the tower through which the screenings and sludge are shot into the tank boat about 20 feet below. This tower was not very well cleaned and when I stepped into it, I could get the strong pig-pen odor easily, though the wind was blowing briskly.



We then took the city launch and went to the outfall of the effluent from this plant. This is shown in the accompanying photograph No. 4. This was about a 30 inch sewer, discharging at the shore and about 5 feet above the water level at the time of my visit. There was a barge anchored directly below this outlet and some carpenters were doing some repair work on the barge. There was no serious nuisance at this outlet. The sewer was only flowing about 3 inches full.

From here we went by the city launch to the old plant, and on the way there was good opportunity to observe the Elbe water. (See photograph No. 4.) This was in all places a yellowish brown, without many large floating matters. The river was very choppy (and they say always is), so that there was very little opportunity for sleek to collect on the surface. Here and there, I saw a few blotches of it, say about 12 inches in diameter. As we came within

12 100 yards of the plant, there was a slightly noticeable sewage odor (I found out afterwards that this probably came from the sludge boat).



The buildings and grounds of this plant were also attractive. Entering the screen room there was, of course, a sewage odor, but this was not noticeable outside the plant. The sewage appeared fresh (fresher than at the south district plant) and did not smell strongly. The depth of sewage in the grit chamber, I measured to be 3 meters (9.8 ft.). It was flowing through at a good velocity (much faster than at the new plant). I timed the screens to be traveling at about the rate of 30 cm. (11.8 inches) in 8 seconds. After this we went to the tower through which the screenings are discharged into the barge. Here again was the strong pig-pen odor.

After visiting the plant, we went in the city launch to just over the outlets. Ing. Helmke pointed out the general location to me by some small floating matters and a white foam or froth on the water surface. There were sea-gulls flying about this part of the river, although I had seen them nowhere else. On the day of my visit, it was cool and there was a good breeze blowing from just west of north. The river was very choppy. I could not see any marked evidences that sewage was being discharged into the river, except the gulls. That is, the water was not discolored and there was no marked sewage odor from the river water at the outlets.

No. 6.
Hamburg Screening Plants
Tank Boat at Point of Disposal of Screenings.

(Exhibit No 204)

No. 7.
Hamburg Screening Plants
Derrick and Dump for Sludge and Screenings.

The only strong odor came from the sludge and screenings. The evidences of sewage discharge were the slight clusters of white froth and the few floating particles.

13 Visits made Aug. 31.—I went first to the old plant, arriving there about 9:50 A. M. The outlet gates were closed and the sewage was standing in the grit chamber. I was told that this had been so for about half-an-hour. The depth of sewage on the fixed gauge was 4.57 meters (14.9 ft.) or 1.57 meters (5.1 ft.) higher than yesterday afternoon.

The day engineer at the plant told me this morning that, during stormy weather, the gulls flocked thickly over the sewer outlets.

The sewage in the grit chamber was bubbling somewhat, but the odor was not objectionable. The temperature of the sewage in front of the screens was 20.5° C. (68.9° F.).

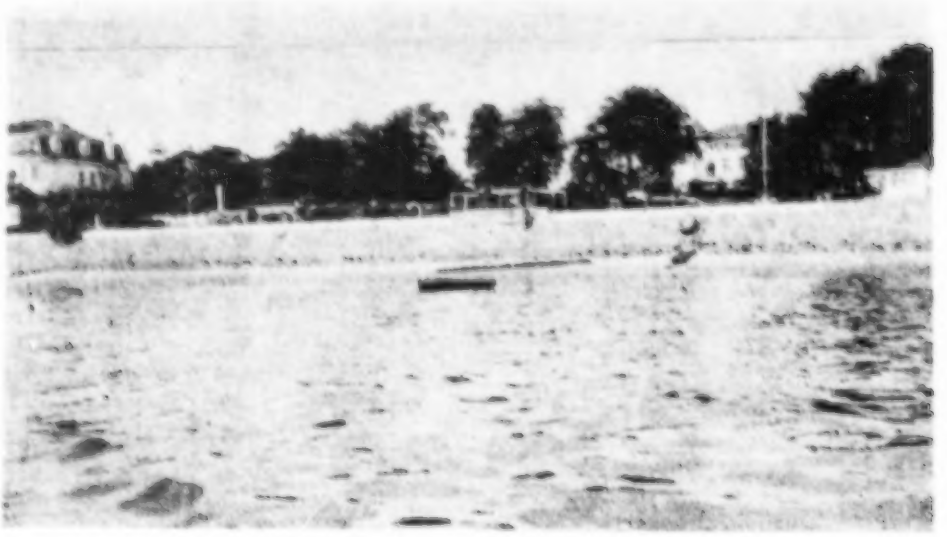
At 10:10 I took a launch with an English speaking engineer and went to Newenfelde, where the screenings from the plants are disposed of.

(Here follow photos marked Nos. 6 and 7, page 14.)

15 We reached Newenfelde about noon and had a two mile walk to the small unloading station where the tank boats from the sewage plants are unloaded. The country we walked through was wholly devoted to truck gardens and orchards, and the whole neighborhood smelled of the pig-pen odor from the sewage screenings used as fertilizer. We saw it lying on the fields.

The unloading station is located on a small creek and was very foul. It consists of only an inlet for docking the tank boat, a derrick, some trucks and a narrow-gauge, movable track. (See photographs Nos. 6, 7 and 8.) The derrick is used to lift the body of the truck from the frame to the boat. There it is filled with a shovel and then replaced on its frame, and the whole car is then run out onto the dump. This dump was about 5 feet deep and 75 ft. by 50 ft. in area, and was very foul. The farmers come and cart this material away, paying 1 M. and 20 pf. per cbm. (22.3 cents per cu. yd.).

Coming back in the launch, I took especial notice of the well-kept beaches along the Elbe, where there were sailing boats and small row boats for hire. Here and there were bathing places. These were located within two miles of the sewer outlet and down stream. (See map and photograph No. 9.) The shore below the outlet did not show evidences of serious pollution.



On the way back, I took samples of the Elbe water at approximately the points marked on the map. The samples were taken by dipping the bottle, on the end of a string, into the river and taking the first bottle full as a sample. I took the temperature at points marked (1) and (4) and in both instances it was 19° C. (66.2° F.).

Here follow photos marked Nos. 8, 9 and 10, pages 16 and 17.)

18 As we returned, there were gulls flying over the outlet. I photographed these, as shown.

Description of samples of Elbe water.—On the trip back on the launch, I took six samples of Elbe water at the points marked on the accompanying map. The samples were taken about six inches below the surface, and were secured by dipping the bottle on the end of a string, the first bottle full being taken. These six samples I took back to my room and photographed them, as shown on the accompanying photograph No. 10.

All the samples were colored a yellowish brown, which did not increase on standing twenty-four hours. In each of them there was a fine "mucky" sediment. I tried the relative turbidity of the samples by the clearness with which I could see the lines of a sheet of paper (similar to the attached sheet) when looking vertically through the water. The bottles were about 5 inches deep.

Bottle No. 2 showed the greatest turbidity. The lines of the paper were just visible when observed near a window one hour before sunset, with no direct sunlight, on, a perfectly clear day. Samples Nos. 1, 4 and 5 were next in degree of turbidity. Then came No. 6, with No. 3 the clearest. There was very little to choose between Nos. 1, 3, 4, 5 and 6, No. 2 being distinctly darker than the others.

All the samples had a slight salty, fishy odor, which did not increase perceptibly after twenty-four hours. There was a fine sediment in the bottom of each bottle, and there was much
19 finely divided suspended matter throughout the water. The yellow color was the greatest mark.

The accompanying photograph (No. 10) shows the six bottles with a glass of clear water in the center. Sample No. 2 is the second bottle from the right of the picture.

I was unable to obtain any analyses or observations of the microorganisms in the Elbe water. However, I secured a book entitled as follows:

Hamburgische Elbe-Untersuchung.

I.

Allgemeines über Die Biologischen Verhaltnisse der Elbe bei Hamburg und über die Einwirkung der Sielwässer auf die Organism des Stromes.

Von Richard Volk.

1903.

This book gives data on both the chemical and biological contents of the river water. It is attached as Appendix V.

Summary of Observations.—1. That the discharge of the effluent from the sewage screening plants of Hamburg into the Elbe did not add seriously to the turbid appearance of the water, the Elbe itself being a colored turbid water at that point.

20 2. That the absence of a discernable sewage field was due to the dispersing of the sewage in the water through the agency of the ships, tugs and tides which intersect the water at many angles and keep the water continuously churned up.

3. That there were evidences of sewage pollution, such as the presence of gulls, the sleek near the docks and the floating particles.

4. That the greatest nuisance from the plants came from the handling of the sludge and screenings at the plant and from their ultimate disposal on land.

21 *Dresden.*

September 2nd.

Description.—Dresden is a city of about 550,000 people, situated on the River Elbe in the central eastern section of Germany. The river divides the city into a larger southern district called "The Old Town" and a smaller northern district called "The New Town." There are no other important streams or canals flowing through the town, and the sewage from both districts flows to one main disposal station below the city and then into the Elbe. At this disposal station, the sewage is screened before entering the river.

Unlike Hamburg, Dresden is not a great shipping center, but has what one might call "an average" population. That is, there is no great preponderance of any one class of population. The trades wastes do not form as important a part of the sewage as at Hamburg.

The Elbe river, as it flows through Dresden, is a fresh water stream, dark in appearance, with a velocity (as I observed it) of less than four miles an hour. At the time of my visit, the surface was smooth and there was some sleek evident on the surface near the shore even above the sewer outlet. The river is not used greatly for shipping, but there are a good many small river steamers and barges anchored along the bank (during my visit the water was too low for many of them). There are several bathing houses along the river, showing that the water is used for bathing, but the water supply for the town is taken from springs and wells, and not from the river.

(See map, Appendix VI.)

22 The quantity of water flowing in the Elbe and the quantity of sewage reaching the disposal works were given to me by Dr. Neidner, with whom I talked at the city hall, as follows:

Elbe:

Minimum flow—50 cbms. per sec. (1,141,214,800 gal. per day).

Normal flow—100-300 cbms. per sec. (2,282,428,800—6,847,268,400 gal. per day).

Maximum flow—6,000 cbms. per sec. (136,945,728,000 gal. per day).

Dry-weather sewage:

A daily average flow of 100,000 cbms. (26,417,000 gal.)

A daily variation of from 500 to 2,000 litres per sec. (11,412,144 to 45,648,576 gal. per day), the maximum occurring between 11 A. M. and 14 P. M.

Storm sewage:

A maximum of 18,000 litres per sec. (410,837,184 gal. per day). This exceeds the capacity of the four screens and part of the flow is by-passed directly into the river.

During my visit the river water was flowing at the minimum rate of 50 cbms. per second (1,141,214,800 gal. per day) and the sewage was about 1/25 of the river water. These are extreme conditions.

Dresden is sewered on the combined plan. There are two main intercepting sewers—one on each side of the river. These flow down stream with an approximate slope of 1 to 3000, and the flow in them is rapid. The superintendent at the screening plant (who speaks English quite easily) told me that the time of flow of sewage from the center of town to the disposal plant was only about one-half hour, and the time of flow for most of the sewage did not exceed 2¼ hours from the point of entrance into the answer to the disposal plant.

23 The disposal plant, where the sewage is screened, is located well below the town in open country, on a large tract of farm land owned by the city. It is located on the north side of the Elbe. The sewage from the southern district passes under the Elbe in a siphon near the west end of the city. Just in front of this siphon is a grit chamber. The sewage from the north district comes direct to the plant, but passes through a grit chamber just before reaching the disposal plant.

The Disposal Works.—The two main sewers, after passing through the two grit chambers, come together near the disposal works, where the sewage is treated before flowing into the river. (See descriptive pamphlet, marked Appendix VII.)

The disposal works consist of

1. An office building.
2. A house in which are located coarse bar screens and scum boards.
3. A main screen house in which are located four of the large disc type screens.
4. A pumping station.
5. A house for the workmen.
6. By-pass conduits for the rain water.

The buildings housing the apparatus, offices, etc., are all large and attractive. The rooms are high, the areas are ample and the yards are large and well paved. The city owns a large tract of land about the works, but does not now use it for farming purposes.

24 There are no buildings within half a mile of the plant, and the location is not at all critical.

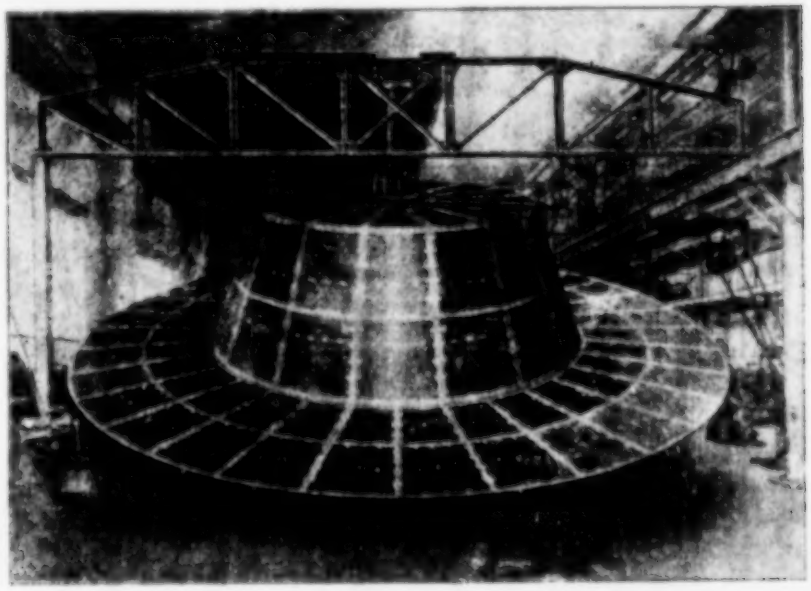
It should be stated that, except the two grit chambers, there is no opportunity for sedimentation of the sewage at the plant. The velocity of the sewage flowing through the works is rapid, so that few deposits are made.

In the preliminary screen house the coarse bar screens are arranged in duplicate, each side having three tiers or sets of screens. The spacing of these screens, beginning at the bottom, is approximately 2″, 4″ and 6″ respectively. They all slope at about 60° with the horizontal, and each tier is provided with an accessible platfrom from which a workman rakes the screen clean. It is sometimes necessary to clean these screens once every thirty minutes. But generally once every four hours is sufficient.

The main revolving, mechanically cleaned screens are of the "Riensch" disc type and are 8 meters (26.24 ft.) in diameter. They are described in the accompanying pamphlet. As shown, these screens are revolving discs of perforated brass plates, fitting around the lower circumference of a truncated cone of brass plates. Each of these screens has a total open area of 14 sq. meters (16.74 sq. yds.). They revolve at two speeds, e. g.—1 revolution per 2 minutes and 1 revolution per 3 minutes. They are run generally at the lower speed. The slits through which the sewage passes are 2 mm. (.078 inches) wide on top, 3 mm. (.117 inches) wide on the bottom and 30 mm. (1.17 inches) long. The brass plates are 5 mm. (.196 inches) thick on the disc and 4 mm. (.157 inches) on the cone.

25 Each screen has a normal capacity of 650 gallons per second (56,160,000 gal. per day), and in dry weather one screen handles the whole flow. Maximum flow requires the operation of all of the four screens.

The maximum loss of head in going through a screen is 60 cm. (23.6 inches), and when this is reached, either the speed of the screen is increased or another screen is cut in.



The screens are cleaned by revolving brushes, which scour the screenings off the screen into a conveyor, which discharges them into small cars in which they are conveyed to the dumps in the yard.

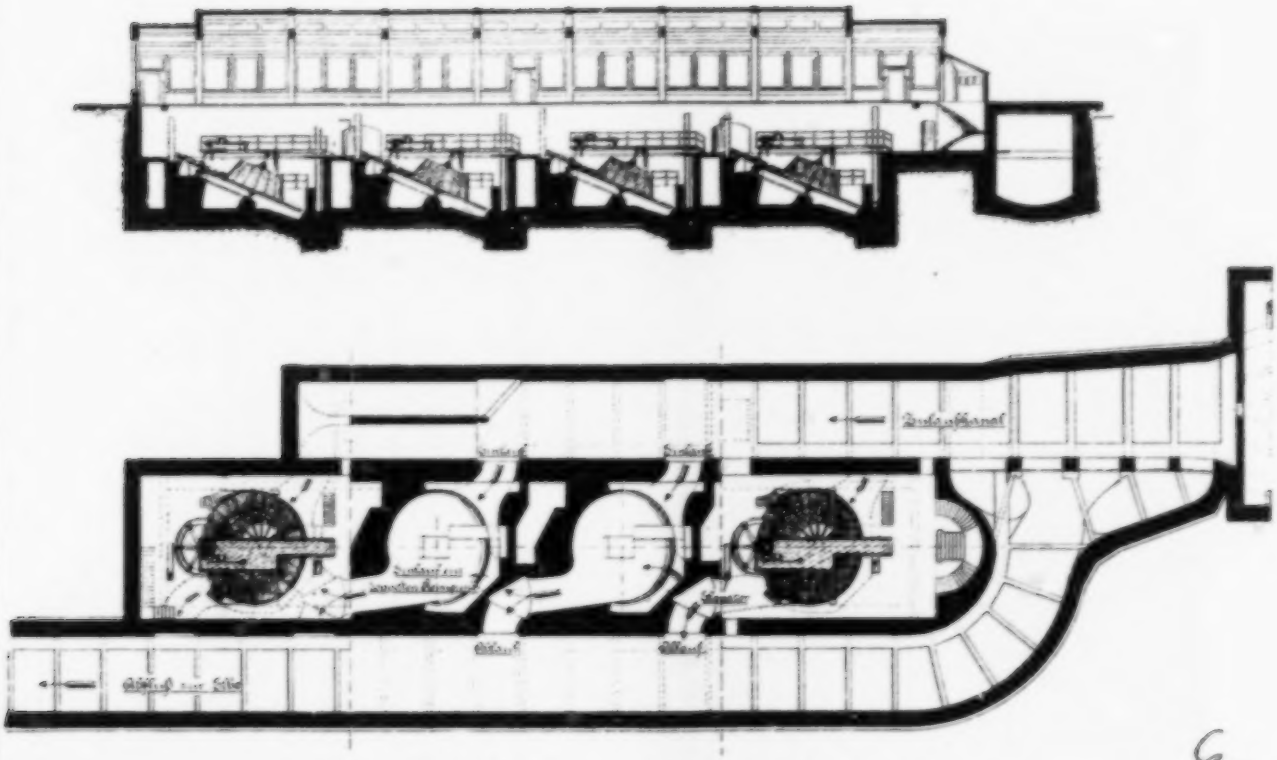
Each screen requires 2½ to 3 h. p. for its operation. (See Plate I for pictures and drawings of the screen.)

(Here follows diagram marked figure 23, page 26.)

Definitive Anlage Dresden

Weiterhin führe ich noch einige Photographien von Scheiben an, die augenblicklich in meiner Werkstatt ihrer Vollendung entgegensehen. Von diesen Scheiben dürfte die definitive Ausführung für die Stadt Dresden wegen ihrer ausgedehnten Dimensionen von besonderem Interesse sein. Wie aus dem in Figur 24 angegebenen Aufriß und

(Exhibit No 204)



Figur 23.

Anlage Dresden in Werkstatt montiert, 8 m Durchm.

Grundriß der Kläranlage zu ersehen ist, sind für die Dresdener Ausführung zunächst 4 Scheiben von je 8 m Durchmesser vorgesehen, die zusammen im Maximalfalle 18000 Sekundenliter Schmutzwasser bewältigen. Die Scheiben sind mit gefrästen Bronzeblechen von 2 mm Schlitzweite versehen und so in den Abflußkanal eingebaut, daß sie einen Wasserstand von 2,4 m beherrschen. Einzelheiten der Scheibe sind aus der obenstehenden Figur 23 ersichtlich. Die gesamten Abwässer Dresdens durchfließen diese Reinigungsanlage und laufen alsdann ohne weitere Reinigung der Elbe zu. Bei Hochwasser werden sie nach Passieren der Separatorscheibe in die Elbe übergepumpt.

Plate I.

Screening Plant at Dresden.

Figur 24 Anlage Dresden, 4 Scheiben je 8 m Durchm.

Ex. 204

27 The pumping station is used only during times of high water in the river. It consists of nine electrically driven, two-stage centrifugal pumps, having a combined capacity of 2250 horse power.

The total cost of the disposal works without land, but including the pumping station, was two and a quarter million marks ($562,500.00).

Work Done.—I spent two days in Dresden—Saturday and Sunday, Sept. 2nd and 3rd. Saturday morning I called on Dr. Ing. Neidner in the city hall, and in the afternoon visited the sewage works, where I was shown around by Ludwig Scheitzow, the superintendent of the plant. Mr. Scheitzow spoke very good English.

General Conditions During Visit.—The two days that I spent at Dresden were both hot, clear, sunny days, with the thermometer at about 80° F. There was no rain on either day, and there had been almost no rainfall for several weeks previous. The Elbe was at its minimum stage.

Visit to Disposal Works—Sept. 2nd.—I went to the sewage disposal works by trolley along the south side of the river as far as Mohn street. From there I walked along the river, then through a suburb, and finally through open fields to the plant—a total walk of about 1.5 miles. I reached the works about 3 P. M. Mr. Scheitzow took me through the plant.

28 I learned from him that the approximate quantities of material removed from the sewage at the disposal works were as follows:

(*a*) From the two grit chambers, one cbm. (1.3 cu. yds.) daily.

(*b*) From the scum boards and bar screens, one cbms. (1.3cu. yds.) daily.

(*c*) From the revolving screens, 10 (13.0 cu. yds.) to 12 cbm. (15.7 cu. yds.) daily.

We went first to see the coarse screens and scum boards. The scum boards were not giving good results, because the velocity of sewage passing them was too great, and they were making trials with different arrangements of the boards. The sewage flowing into the plant here was quite fresh and had no strong, disagreeable smell.

At the time of my visit, only one of the disc screens was in operation, and the difference in level of the sewage on the two sides was only 30 cm. (11.8 inches.)

I was told that the disc screens sometimes required washing with a hose once every hour to remove fat and grease. At other times, one washing on each eight-hour shift is sufficient. One man can look after the ordinary operation of all four screens.

The material removed from the sewage is piled in the yard and either given away or sold as a fertilizer. The material from the grit chambers is a black, sandy substance that dries to an earth like street dirt. I examined a long pile of it in the yard, and the odor was almost imperceptible. The material from the bar screens is black and earthy, with more leaves, rags, etc., in it than in the

material from the grit chambers. I saw a long pile of this in
29 the yard, and the odor was slight. These two materials are only fair fertilizers and are given away to the farmers. The screenings from the disc screens are taken to long wooden troughs in the yard. These troughs have false bottoms built like grills, so that the liquid from the screenings can drain out and flow back to the plant. The troughs are roofed over, but not housed in. In them the screenings drain and dry, so that from 100 cbm. (130.7 cu. yds.) of raw screenings, there is left only 30 (39.2 cu. yds.) to 40 cbm. (42.3 cu. yds.) of dry material. This is said to be a very good fertilizer, and farmers take it away, paying 50 pf. a cbm. (about 10 cents per cu. yd.) There was no accumulation of it at the plant. This material was very offensive, giving off the characteristic pig-pen odor.

Attached is a very complete description of the works, dated August, 1911. The quantities given to me by the superintendent are somewhat more liberal than those quoted in the articles. This is marked Appendix VII.

Conditions of River Water Below the Plant.—I walked from the plant down along the river about one-third of a mile to the sewer outlet, and then about half a mile farther down to a ferry, where I crossed over to the north side of the river. The river water was dirty and dark-appearing all the way down. At the outlet there was no perceptible bubbling up of sewage, nor any further discoloration evident from the shore. No sea-gulls were in evidence. From the sewer outlet to the ferry, I noticed a slight but distinct odor and there were a few blotches of sleek evident on the surface.
30 Near the ferry two men on the bank were fishing and about half-a-mile below the ferry some boys were in swimming.

As I walked along, the velocity of floating particles on the surface was about 2½ to 3 miles per hour.

Around the wharf where the ferry landed, and at logs along the shore, scum collected to a slight extent.

Summary of Observations.—1. That the discharge of the effluent from the sewage screening plant of Dresden into the Elbe increased the unpleasantness of the river water.

2. That there were evidences of sewage pollution, such as the sleek which collected along the shore, the floating particles and the sewage odor.

3. That the greatest odor from the sewage treatment came from the storage and distribution of screenings.

31 **Frankfort.**

September 4th.

Description.—Frankfort is a city of about 420,000 people in Germany, on the River Main, in the southern part of Germany. The greater part of the town lies north of the river. There are no other important streams or waterways in the city. Frankfort is more of a

commercial and manufacturing city than Dresden, but not so much as Hamburg. The sewage, however, contains more solid matter than is found in the sewages of most German cities, the amount of solids being about 1300 parts per million. (For map of city see Appendix VIII.)

The city is sewered on the combined system, and the sewage from the whole city is clarified at one disposal plant located on the south side of the river, about one mile below the city. The disposal plant is located on a large tract of land owned by the city, and is not near many houses. The city refuse incinerator is adjacent to the sewage disposal works. These disposal works are different from those at Hamburg and Dresden, because in addition to removing the heavy suspended matter in the grit chamber and some of the coarser suspended matter on the screens, they also further clarify the sewage in settling basins. In this way a greater proportion of the "settleable" solids is removed, but there are more opportunities for the sewage to become septic. The percentage removal in the different stages of the clarification are given as follows, the percentages being based on the total suspended solids in the raw sewage:

32

Removed in grit chamber and screens	21%
Removed in settling basins	56%
Total removed	77%

This data is published in the accompanying descriptive pamphlet marked Appendix IX.

As is common in German cities, the sewers are well built, with good slopes, and the sewage comes to the plant in a fairly fresh condition. I should say, however, that it was not as fresh as at Dresden and Hamburg. The daily sewage flow to the plant generally varies from 85,000 cbm. (22,454,450 gal.) to 120,000 cbm. (31,700,000 gal.). The sewage from the north side is siphoned under the river to the disposal plant.

The Main was very low at the time of my visit. The quantity of water flowing in the river was given to me as follows:

Minimum flow	70 cbm. per sec. (1,597,700,160 gal. per day)
Average flow	100 " " " (2,282,428,800 " " ")
Maximum flow	300-400 cbm. per sec. (6,847,286,400—9,129,715,200 gal. per day)

At the time of my visit, it was a dark, unsightly water having a surface velocity of two to three miles per hour. I could easily walk faster than particles floating on the surface. The river is used for small boats and barges. The shipping is increasing but is not great, and the surface was smooth; there was comparatively little agitation of the water by boats. There are bathing places on the river front in the city and above the sewer outlet.

33 Disposal Works.—The sewage disposal plant consists of:
(1) A grit chamber.
(2) Three screens of the revolving paddle wheel type.
(3) Fourteen covered settling basins.
(4) Sludge pumping machinery.
(5) Centrifugal machines for drying the screenings and sludge.
(6) Conveyors, conduits, by-passes for rain water, etc.

The grit chamber and screens are located together in a house of substantial and attractive brick construction. The settling basins are covered over with an arched roof, which supports a well laid out lawn, cut with paths and gardens. There are numerous flower-beds about the plant, which is very attractive to look at. There are also attractive offices and quarters for the workmen.

The grit chamber is 6 meters (19.7 ft.) long and about 12 meters (39.4 ft.) wide, and has a bottom with rounded corners into which a cup conveyor fits. This conveyor is on a traveling carriage, so that by swinging the conveyor and moving the carriage the whole grit chamber can be cleaned. I was told at the plant that the quantity of sand removed from the grit chamber amounted to from 10 (13.0 cu. yds.) to 15 cbm. (19.9 cu. yds.) per day, and that it was cleaned daily. The grit is taken to the centrifugal machines, where it is dried and then burned in the incinerator.

There are three screens, each having five paddles and each requiring 3 h. p. to operate it. Each screen is 2 meters (6.6 ft.)
34 wide, and the clear spacing between the bars is 10 millimeters (0.39 inches). The screens are cleaned mechanically by brushes which force the leaves, rags, feces, etc., off the end of the paddles on to a belt conveyor. The screens take from 2 to 4 minutes per revolution, and the speed can be varied to suit the flow of sewage. I was told at the plant that the screens removed from 15 (19.9 cu. yds.) to 20 cbm. (26.1 cu. yds.) daily.

Each of the fourteen settling tanks is 5.8 meters (19.0 ft.) wide by about 41 meters (134.5 ft.) long and 2.5 meters (8.2 ft.) deep. The velocity of flow in them is not over 8 millimeters (0.312 inches) per second, and the period of flow is about 80 minutes. From 6 to 8 tanks are in operation at a time. Each tank is allowed to run for ten days, when the supernatant sewage is drawn off and the wet sludge is pumped to the centrifugal machines. When drawn, each tank contains about 400 cbm. (522 cu. yds.) of wet sludge. Therefore the daily quantity of sludge from each tank amounts to about 40 cbm. (52.2 cu. yds.) and with seven tanks in operation, this would amount to 280 cbm. (366 cu. yds.) daily of wet sludge. Six tanks were in operation at the time of my visit.

The bottom of each basin slopes toward two sumps, from which the sludge is pumped to the centrifugal machines. The basins are lined with white glazed brick, to avoid deposits and to facilitate cleaning. The pumping is done by two vacuum tanks, which operate like suction pumps delivering into a force main. They pump the sludge through an iron pipe 30 cm. (11.8 inches) in diameter
35 to the centrifugal machines about 200 yards away. The difference in elevation between the settling tanks and the sludge

tanks of the centrifugal machines is about 17 meters (55.7 ft.) and the dynamic head is 25 meters (82.0 ft.)

The sludge drying plant consists of four sludge tanks over the centrifugal machines, eight so-called centrifuges, a hot air drier in the basement, and the necessary hoists and conveyors for delivering the dried sludge into the hoppers over the furnaces of the incinerator. Each centrifugal machine has a capacity of 3 cbm. (3.9 cu. yds.) of wet sludge per hour, and it is necessary to keep 4 to 6 machines running every day. The drier in the basement is heated with waste gases from the incinerator.

It is interesting to note that up to the latter part of the year 1909, the sludge and screenings from the Frankfort plant were disposed of on land. On account of the unreliability of this method of sludge disposal, the centrifugal machines described above were installed. This is a costly method of disposal, but gets the sludge and screenings out of the way without great nuisance.

Work Done.—I spent only Monday, Sept. 4th, in Frankfort. In the morning I went to the city hall and talked with Ing. Schaefer, and in the afternoon I visited the disposal works, where I was shown through by the chief foreman in the absence of the superintendent.

General Conditions During Visit.—The day of my visit was a clear, hot, sunny day, with very little wind; the temperature
36 being about 80° F. There was no rain on that day and there had been almost none for several weeks previous. The Main was very low.

Visit to Disposal Works, Sept. 4.—I went to the disposal works partly by trolley and partly on foot. From the trolley I walked down along the river bank for about three-quarters of a mile. Along this part of the river there were quite a number of gardens and there were houses up to about three-eighths of a mile from the works. Just before coming to the works, I passed the unloading station, where the scows bringing the refuse boxes from the city are unloaded. The neighborhood was not critical but was not so isolated as at Dresden.

I went first into the house containing the grit chamber and screens. The velocity through this part of the works was quite rapid (say about 4 feet per second), and the odor was not bad. One of the screens was not operating on the day of my visit.

Going into the tank house, the odor was more distinct. In the masonry roof over each tank there is an opening or vent, through which the gases from the tanks escape. I afterward went close to one of these vents where it opened into the air and got no very bad smell.

Six tanks were in operation when I was at the plant, and all of them had a heavy scum, especially the main distributing channel at the center.

The centrifugal house smelled like a reduction plant, only not so strongly. This odor came from handling the dried sludge in the cars and conveyors. The odor was not so strong as the odor from the screenings at Dresden and Hamburg. The material coming
37 out of the drier was a black, moist, fine, earthy material that smelled like the tankage from a garbage reduction plant.

Condition of Main Water.—After going through the plant, I went down to the main sewage outlet below the plant. There was one seagull there, and the foreman told me there were many there during stormy weather. Two or three miles below, I could see the chimneys of a small town. The effluent was discharged about one-fourth of the width of the river from shore. The effluent was very plain to see as it "boiled" up out of the dark river water. It looked like a thick, light-brown colored liquid, and it made a long, clearly marked area in the river water, extending for at least a quarter of a mile below the point of discharge.

I was told that at this point the river was about six meters (19.7 ft.) deep and that the bottom was gravelly; and that no deposits formed on the bottom.

The odor from the effluent was faint—not as evident as at Dresden.

Summary of Observations.—1. That the discharge of the effluent from the sewage disposal works of Frankfort into the Main materially increased the unsightliness of the river water.

2. That there were evidences of sewage pollution, such as the boiling or bubbling up of the sewage plant effluent in the river water and the clearly marked sewage area extending down stream from the point of discharge.

38 3. That the city, after disposing of the sludge and screenings on land for a number of years, had gone to great expense to dry and then burn the sludge and screenings from the sewage works.

Respectfully submitted,

SAMUEL A. GREELEY.

39 APPENDIX I.

List of Drawings and Documents.

Those secured:

(1) Tide tables for Hamburg, 1911 (Appendix II.)
(2) Die Sielanlagen Hamburgs (Appendix III-A).
(3) Hamburger Förderrechen (Appendix III-B).
(4) Map of Hamburg (Appendix IV).
(5) Hamburgische Elb-Untersuchung (Appendix V).
(6) Map of Dresden (Appendix VI).
(7) Beschreibung der Anlagen zur Reinigung und Hebung der Dresdner Kanalwasser (Appendix VII).
(8) Map of Frankfort (Appendix VIII).
(9) Müllverbrennungs und Abwasserklär-Anlage Frankfort-am-Main (Appendix IX).

Those to be secured:

(1) A description of the Hamburg sewers and sewage disposal works—by Curt Merkel.

(2) Der Wasserbau—Die Eutwasserrung der Stadte—by August Frühling (gives some data on stream flow).

(3) Wasser und Abwasser—Die Hygiene der Wasserversorgung und Abwasserbeseitigung—by Kollwitz, Reichle, Schmidtman, Spitta, and Thumm. Verlag S. Hirzel, Leipzig, 1911.

(4) Maps of Germany may be secured from Die Kgl. Preussische Geologische Landesanstalt Berlin.

Photographs—Ten of sewage works at Hamburg.

APPENDIX II.

Tide Tables for Hamburg, 1911.

(Here follows reproduction of four pages of tide tables for Hamburg.

42 Hundbuch der Hygiene, by Thumm-Schmidtman, etc.

1911.

Summary of all work done at Royal Testing Station & throughout Germany.

(Exhibit No 204)

Die Finsternisse des Jahres 1911.

Im Jahre 1911 werden zwei, für unsere Gegenden nicht sichtbare, Sonnenfinsternisse stattfinden. Der Mond wird in diesem Jahre nicht verfinstert.

Die erste Sonnenfinsternis ist eine totale und ereignet sich in der Nacht vom 28. zum 29. April. Sie beginnt bei der Lord-Howe-Insel im Osten von Australien am 28. April um 8 Uhr 49 Min. abends, überstreicht die östliche Hälfte des australischen Kontinents und Neu-Seeland, zieht über die Mitte des Stillen Ozeans und erstreckt sich über Mittelamerika und die südliche Hälfte Nordamerikas. Sie endet am 29. April um 2 Uhr 6 Min. morgens in der Gegend zwischen Acapulco an der mexikanischen Küste und der Clippecton-Insel.

Die zweite Sonnenfinsternis findet am Vormittag des 22. Oktober statt. Sie ist eine ringförmige und beginnt um 2 Uhr 19 Min. morgens in der Nähe von Lahore. Das Gebiet der Sichtbarkeit erstreckt sich über den größten Teil des asiatischen Kontinents mit Ausnahme von Kleinasien, Palästina, dem westlichen Arabien und dem im Osten der Lena gelegenen Teil Sibiriens; ferner über Australien mit Ausnahme der Südwestspitze des letzten en und über die westliche Hälfte Polynesiens. Die Finsternis endet im Südosten der Salomon-Inseln um 8 Uhr 7 Min. vormittags.

Geschichtliche Erinnerungen.

Das Jahr 1911 der christlichen Ära ist das
6624. der Julianischen Periode;
5672. der Juden (Beginn desselben am 23. September, s. S. 3 u. 16);
1946. seit der Einführung des Julianischen Kalenders durch Julius Cäsar;
1841. nach der Zerstörung Jerusalems durch Titus;
1111. seit der Krönung Karls des Großen zum römischen Kaiser;
1108. seit der Gründung Hamburgs (nach alter, nicht völlig sicherer Annahme);
1125. seit Gründung des Bistums Bremen durch Karl den Großen.
1080. seit der Gründung eines Erzbistums in Hamburg durch Ludwig den Frommen;
949. seit der Krönung Otto des Ersten zum römischen Kaiser;
768. seit der Gründung des jetzigen Lübecks;
471. seit der Erfindung der Buchdruckerkunst;
458. seit dem Ende des oströmischen Kaisertums und der Eroberung Konstantinopels durch die Turken;
419. seit der Entdeckung Amerikas;
394. seit dem Beginn der Reformation durch Martin Luther;
329. seit der Kalenderverbesserung durch Papst Gregor XIII.;
290. seitdem die Neustadt (das spätere Michaelis-Kirchspiel) zur Stadt gezogen wurde;
135. seit der Einführung des „allgemeinen Reichs-Kalenders";
69 seit dem letzten großen Brand in Hamburg (5. bis 8. Mai 1842);
56. seit der letzten großen Sturmflut (20' 1");
52. seit der Einführung der neuen Verfassung in Hamburg;
43. seitdem die Vorstadt St. Georg zu Hamburg gezogen wurde;
41. laufende Jahr von der Neubegründung des Deutschen Reiches im Januar 1871 an;
23. seit dem Tode Kaiser Wilhelms I.

Mitteleuropäische Zeit. (M. E. Z.)

Alle Angaben in diesem Kalender sind auf M. E. Z. berechnet. Für Sonnen- und Mond-Auf- und Untergang gilt die Breite und der Meridian von Hamburg. Die nachfolgende Tafel gibt die Differenzen zwischen M. E. Z. und M. O. Z. Um mittlere Ortszeit zu bekommen, hat man zu den Zeitangaben des Kalenders für die folgenden Orte + zu addieren — zu subtrahieren.

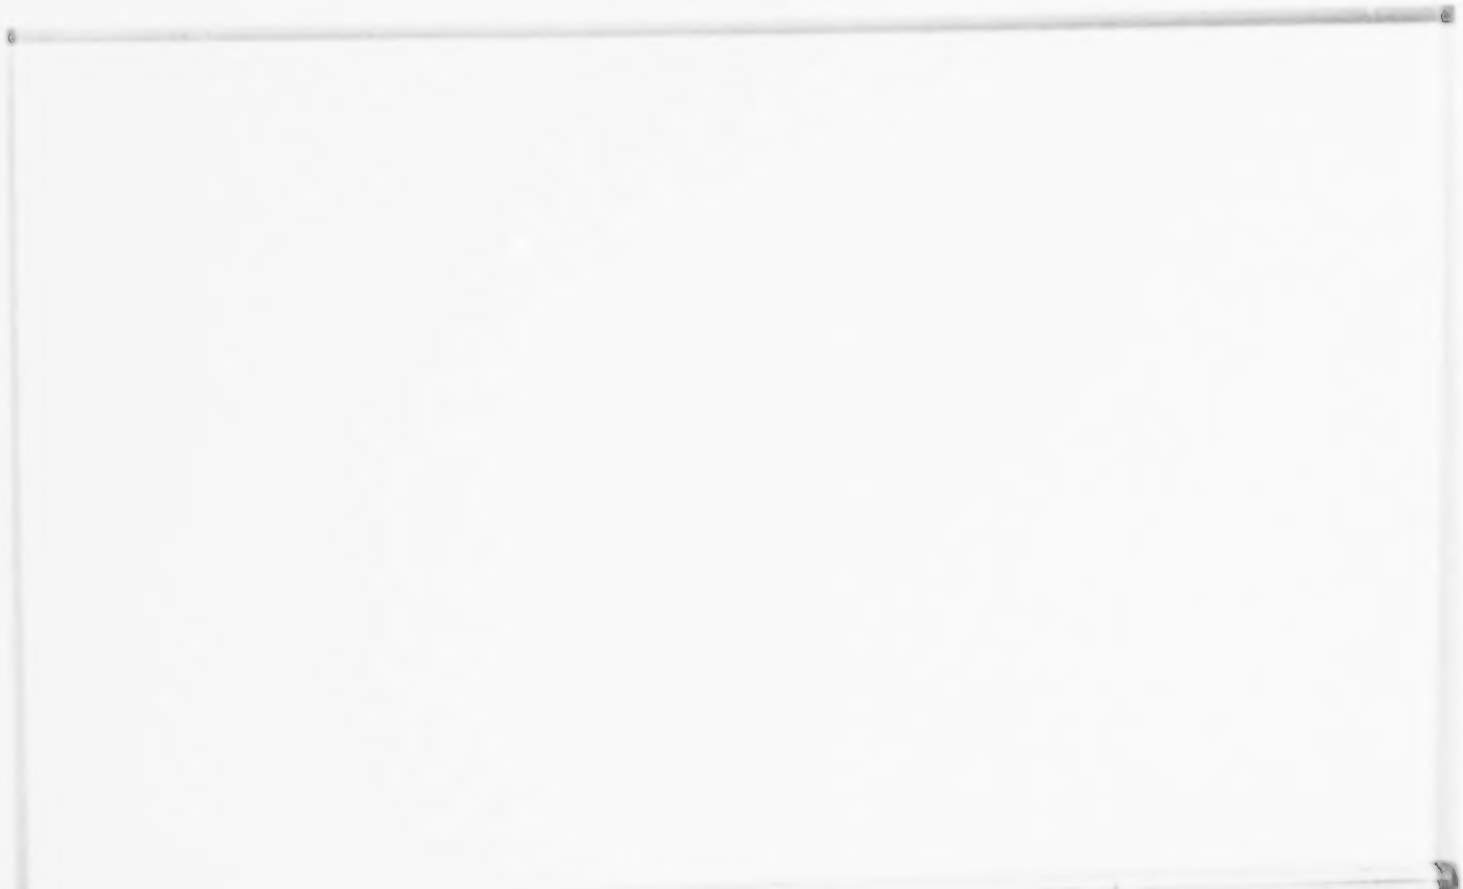
1 COMPLAINANTS' EXHIBIT No. 215. James D. Maher, Commissioner.

Effect of Salinity and Direction of Discharge on the Ascent of Fresh Water in Salt Water.

Edward Ellery.



---

2 COMPLAINANTS' EXHIBIT No. 215. James D. Maher, Commissioner.

Effect of Salinity and Direction of Discharge on the Ascent of Fresh Water in Salt Water.

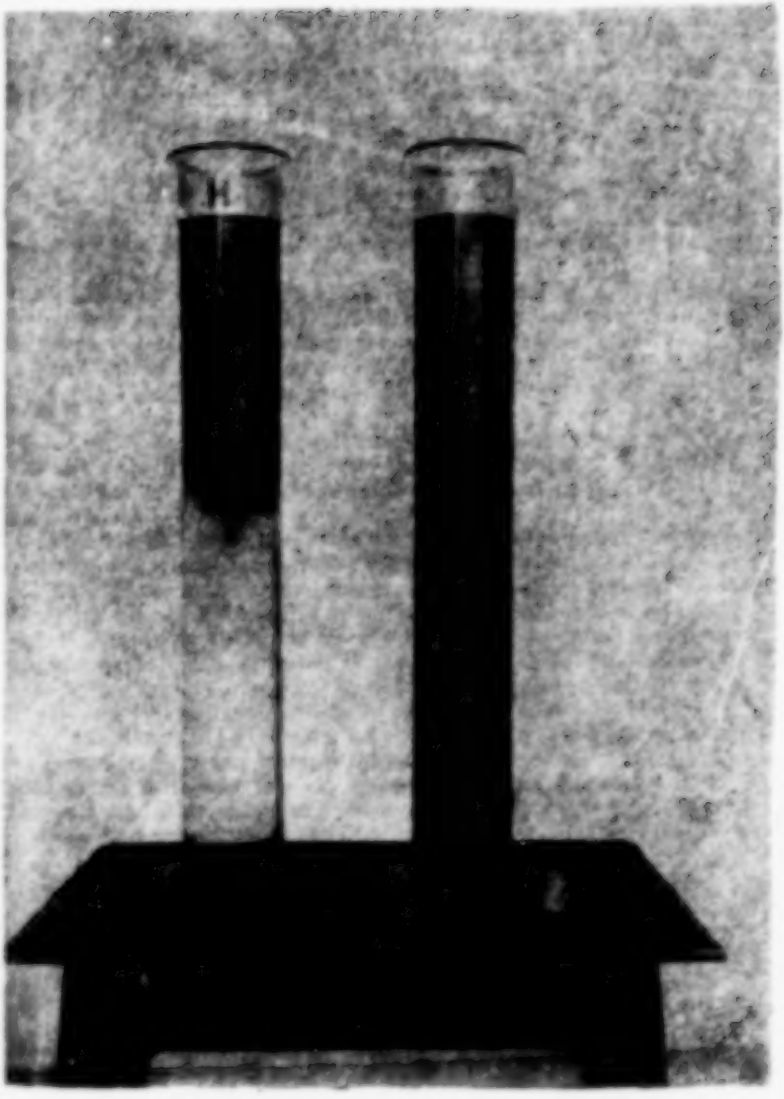
Edward Ellery.

(Here follows diagram showing ascent of fresh water in salt water, marked Exhibit 215, page 3.)

Cylinder "A." Water of 14,019 parts Chlorine per million under fresh water. Dye solution delivered in lower layer in upward direction. After ten days standing.

Cylinder "B." Water of 14,019 parts Chlorine per million under water of 7,009 parts Chlorine per million. Dye solution delivered in lower layer in upward direction. After ten days standing.

Cylinder "C." Water of 6,754 parts Chlorine per million under water 3,377 parts per million. Dye delivered in lower layer in upward direction. After ten days standing.



Cylinder "D." Water of 8,500 parts Chlorine per million under water of 6,500 parts per million. Dye solution delivered in lower layer in upward direction. After three days standing.

Cylinder "E." Water of 8,500 parts Chlorine per million under water of 8,000 parts per million. Dye solution delivered in lower layer in downward direction. After two days standing.

Cylinder "F." Water of 8,500 parts Chlorine per million under water of 7,500 parts per million. Dye solution delivered downward, in lower layer. After two days standing.

Cylinder "G." Water of 8,500 parts Chlorine per million under water of 7,000 parts per million. Dye solution delivered in downward direction in lower layer. After two days standing.

(Here follows diagram marked Exhibit 215, page 5.)

(Enclosed 215, page 5)

6 Cylinder "H." Water of 8,500 parts Chlorine per million. Dye solution delivered about eight inches from the bottom, in an upward direction. After two hours standing.

Cylinder with no letter shows how the waters looked when the dye solution had diffused itself throughout the entire column.

7 *Foreword.*

In his testimony in the case of New York vs. New Jersey and The Passaic Valley Sewerage Commission, Mr. Geo. A. Johnson, witness for the defendant, testified as follows, regarding a certain dye experiment performed by him:

1. 30,000 gallons of water heavily charged with an aniline dye were pumped into the bay, 10, 20, 30, and 40 feet below the surface at rates varying from 1.8 to 2 cu. ft. per second (pages 3976-77).

2. Strength of dye solution was 2/3 of a pound to 1,000 gallons of water, or about 1 part dye in 11,500 parts water by weight (page 3977).

3. The discharge pipe pointed vertically downward (page 3997).

4. At the hour of discharge into the deepest water both surface and bottom currents were of the same velocity and in the same direction (pages 3978-3982).

5. The salinity of the water was 8,500 parts Chlorine per million, about 46% sea water (page 3979-3982).

6. The inference is drawn that when fresh water sewage, discharged as proposed through outlets, some 150 in number, and located at a depth of 40 ft., or more below the surface, will undergo a sufficiently complete diffusion in the waters of New York Bay so as not to rise to the surface in objectionable quantities if at all, and rarely if at all in visible quantities" (page 3982-3983).

The following study shows what conditions must be taken into consideration before any interpretation can be made of the results of discharging fresh water into salt water, and in the absence of such details in Mr. Johnson's testimony regarding his experiment
8 he had no sufficient basis for his inference, and further his inference is erroneous.

Outline of the Experiments.

I. Effect of direction of discharge of fresh water into salt waters when the latter is of the same degree of salinity throughout.

II. Effect of delivering fresh water in an upward direction into salt water consisting of layers of different degrees of salinity.

III. Effect of delivering fresh water in a downward direction into salt water consisting of layers of different degrees of salinity.

General Conclusions.

1. When fresh water is discharged in a downward direction into salt water of the same degree of salinity throughout, it first continues to move downward and then moves upward to the surface.

2. When fresh water is discharged sidewise into salt water of the same degree of salinity throughout, it rises to the surface at once.

3. When fresh water is discharged in an upward direction into salt water of the same degree of salinity throughout it rises to the surface at a more rapid rate that in either case 1 or 2.

4. When fresh water is discharged in an upward direction into salt water consisting of different layers of varying degrees of salinity, it comes to the surface at once, except in cases of large difference in salinity of the layers.

5. When fresh water is discharged in a downward direction into salt water consisting of layers of different degrees of salinity, it rises only to the top of the lower layer and remains there for periods of time varying from two to ten days.

6. Therefore the question of whether fresh water discharged into salt water will come to the surface or not, depends on two conditions; first, the direction of discharge, and second, difference in salinity in different layers of the water into which the discharge takes place.

Apparatus Used in the Study.

For the purposes of this study tall cylinders were used 28 inches high and 4 inches in diameter. These were filled with 4 liters of water. To the water varying amounts of salt accurately weighed were added, and thoroughly mixed to insure the homogeneity of the solution. In the cases in which different layers of water were required in the same cylinder, the heavier water was delivered at the bottom of a lighter water by means of an elongated funnel tube reaching to the bottom of the cylinder.

For delivering the dye solution three long glass tubes were used of the same calibre, one straight throughout its length for delivery in a downward direction, one with a bend at right angle for delivery sidewise, and one with the end bent to deliver the solution in an upward direction. These tubes were graduated in order that the same amount of dye solution might be delivered at each trial and at the same velocity.

Two dyes were used, one known as "Special Scarlet", referred to by the Metropolitan Sewerage Commission in its report for 1910, page 458, and one known as "Red 2R", presumably the one referred to by Mr. Johnson in his testimony (page 3977). These are azo-dyes of similar chemical structure, are both soluble in water to a deep red solution, and both give easily distinguishable color in extremely dilute solutions.

The strength of the solution in each case was eighty parts of dye to a million parts of water, or in other words one part to 12.500, the strength Mr. Johnson used in his experiment (page 3977-3978).

Results of the Series.

I.

Conditions: Homogeneous solution.
Delivery down, sidewise and up.
Time noted when color reached the surface.

Salinity parts chlorine per million.	Delivered down.	Delivered sidewise.	Delivered up.
6,754	Less than 5 min.	Less than 5 min.	Less than 5 min.
7,098	" "	" "	" "
7,266	" "	" "	" "
8,055	" "	" "	" "
9,006	" "	" "	" "
9,590	" "	" "	" "
10,009	" "	" "	" "
13,062	" "	" "	" "
13,703	" "	" "	" "
14,500	" "	" "	" "
16,098	" "	" "	" "
17,098	" "	" "	" "

11 *Conclusion.*

When delivered into salt water varying in salinity from 6,754 parts chlorine per million (36.5% sea water) to 17,098 parts chlorine per million (96.5% sea water) fresh water rises at once to the surface, and the direction of the discharge does not make any further difference than to affect the rate of rise.

II.

Conditions: Two layers, salt water, of different degrees of salinity.
Delivery in upward direction.

For this series cylinders were prepared as follows:

1. Water of 14,019 parts Chlorine per million under fresh water Cylinder "A" of the photograph.

2. Water of 14,019 parts Chlorine per million under water of 7,009 parts Chlorine per million.
Cylinder "B" of the photograph.

3. Water of 6,754 parts Chlorine per million under water of 3,377 parts Chlorine per million.
Cylinder "C" of the photograph.

4. Water of 8,500 parts Chlorine per million under water of 8,000 parts Chlorine per million.

5. Water of 8,500 parts Chlorine per million under water of 7,500 parts Chlorine per million.

6. Water of 8,500 parts Chlorine per million under water of 7,000 parts Chlorine per million.
7. Water of 8,500 parts Chlorine per million under water of 6,500 parts Chlorine per million.
Cylinder "D" of the photograph.

12 *Results.*

1. No color in the upper layer after ten days. All in lower layer.
2. No color in upper layer after ten days. Color diffused through lower layer but most of it at the junction on the two layers.
3. No color in the upper layer, after ten days. Color evenly diffused through lower layer.
4. Color reached the surface in less than five minutes.
5. Some color reached the top in less than five minutes, but heavy line of color was noticeable between the layers after an hour.
6. Some color reached the top in less than five minutes, but heavy line of color was noticeable between the layers after two hours.
7. No color had reached the top after three days.
The photograph shows these results very distinctly and the sharp line of division between the different layers.

Conclusion.

Fresh water delivered upward at the velocity of these experiments in the lower of two layers of salt water of different degrees of salinity, does not rise to the surface if the difference in salinity is 11% or more.

III.

Conditions: Two layers, salt water, of different degrees of salinity. Delivery in downward direction.

In this series a blank determination was first made with five cylinders of water of different degrees of salinity, starting with a water containing 8,500 parts chlorine per million, the salinity observed by Mr. Johnson at the time of his experiment (pages 3979-3982).

13 The following results were noted:

Salinity parts chlorine per million.	Dye solution delivered downward.
8,500	Reached the surface in less than five minutes.
8,000	" " " " " " " "
7,500	" " " " " " " "
7,000	" " " " " " " "
6,500	" " " " " " " "

Cylinders were then prepared as follows:

1. Water of 8,500 parts Chlorine per million under water of 8,000 parts per million.

Cylinder "E" of photograph.

2. Water of 8,500 parts Chlorine per million under water of 7,500 parts per million.

Cylinder "F" of photograph.

3. Water of 8,500 parts Chlorine per million under water of 7,000 parts per million.

Cylinder "G" of photograph.

4. Water of 8,500 parts Chlorine per million under water of 6,500 parts per million.

The dye solution was delivered downward as in the blank in the bottom layer of each cylinder, with the following results, shown very clearly in the photograph:

1. Distinct stratification as shown by the color in the lower layer after 48 hours.
2. Ditto.
3. Ditto.
4. Ditto.

After six days the stratification was still distinct in "4" but the color had diffused in that time throughout the *the* others.

14 *Conclusion.*

When fresh water is delivered downward in salt water consisting of layers of different degrees of salinity, a very slight difference in salinity (less than three per cent) is sufficient to keep the fresh water in the lower layer although the same fresh water will rise through *through* either layer alone.

General Conclusions from I, II, and III.

It is apparent from the foregoing that direction of discharge and salinity in different layers of water into which the discharge takes place determine whether the discharged water will come to the surface or not. It seems therefore that Mr. Johnson's inference, if based upon the data given in his testimony (pages 3976-4011) and on no other, is not warranted and is untenable. It is doubtless true that under some circumstances fresh water when delivered downward into salt water will not come to the surface, but it is equally true that under other circumstances it will come to the surface. A general statement that it will or that it will not come to the surface can not be made.

It is further to be noted that in Mr. Johnson's experiment the fresh water was delivered in a downward direction while in the proposed plan of the defendant the sewage is to be delivered upward. These experiments, herein recorded, show that when fresh water is delivered upward in salt water there are fewer conditions which prevent its coming to the surface than under any other method

of delivery. A conclusion based upon the result of delivering
15 fresh water downward into salt water is not applicable to the condition when the fresh water is delivered upward.

The differences in salinity of the layers of water off Robbins Reef are very clearly shown in the report of the Metropolitan Sewerage Commission for 1910 on page 527. "The difference between the salinity of the water at the surface and at a depth below the surface of 40 ft. was found more marked at Robbins Reef than at most other places, the surface sometimes containing 10% more land water than that near the bottom, but this condition was variable". The table of salinities given on that page of the report shows that the difference of salinity would be great enough at times to keep fresh water delivered in the lower depths downward in that stratum, but would not be great enough to keep the fresh water in the lower stratum if it were delivered upward. The report also shows on the same page that there are times when the conditions are such that the fresh water would come to the surface, whatever the direction of its discharge. The report states—

"A sample taken at Robbins Reef October 30 at 4 P. M. had a specific gravity of 1.025, indicating an entire absence of land water."

This study shows that under those circumstances or any others in which there was homogeneity in the waters fresh water will come to the surface whatever the direction of discharge.

These considerations show that Mr. Johnson did not have sufficient basis for his inference, or having it failed to give it in his testimony. They further show that whether he had more data than he gave or not his inference is erroneous.

a COMPLAINANTS' EXHIBIT No. 216. James D. Maher, Commissioner.

THE AERATION OF WATER.

Special Topic: The Influence of Sewage Pollution.

Edward Ellery.

---

1 COMPLAINANTS' EXHIBIT No. 216. James D. Maher, Commissioner.

THE AERATION OF WATER.

Special Topic: The Influence of Sewage Pollution.

Edward Ellery.

2 *Foreword.*

This study of the influences that affect the rate of absorption by water of oxygen from the atmosphere is not undertaken to determine with scientific accuracy the coefficient of oxygen absorption, but is being carried on with a view to determining what actually takes place in the matter of oxygen absorption under varying conditions. The plan is to study two large volumes of water at the same time and, if possible, to change one of the variables while keeping all the others constant. It is thought that such a study will throw some light on the complex problem of aeration of water from the atmosphere.

The special topic herein treated, namely, "The Influence of Sewage Pollution," is taken up at this time under the direction of Dr. W. J. O'Sullivan, Special Counsel for New York in the case of New York vs. New Jersey and the Passaic Valley Sewerage Commission, and the results are the property of New York, to be used only as counsel in the above case may permit and direct.

General Conclusions.

1. Salt water of from 60% to 70% of the salinity of the sea water seems to absorb oxygen from the air at practically the same rate as fresh water, between the points of 40% and 60% of saturation for each. (See General Conclusions, Series I, pages 11, 12).

3 2. The absorption of oxygen by both fresh and salt water from the air is not so rapid as has been supposed. Dr. Adeney's maximum of 0.067 c. c. to 0.077 c. c. of oxygen per liter per hour seems high in the light of this study. These experiments show that the rate of absorption may vary from 0.18 c. c. per day to 0.306 c. c. per day in quiescent water and to 0.515 c. c. per day in moving water. (See General Conclusions, Series I, Page 12).

3. Whatever may be the cause of fluctuations in the amount of oxygen absorbed, it affects both fresh and salt water in the same way. (See diagram I.)

4. The greater the humidity, the less is the rate of absorption of oxygen by both fresh and salt waters. (See diagram II, III and V. Also Results, Series IIA, page 13). (Also Results, Series IIIA, Page 18.)

5. Polluted salt water absorbs oxygen at a greater rate than unpolluted. (See Results, Series IIA, pages 13; Results Series IIB, page 16; Results IIIA, page 18; Exception in the case of the second day, Series IIIA, page 18).

6. A dilution of the proportion of one part of sewage to sixty (60) parts of salt water, when the water is quiescent, does not seem permissible, while a dilution of 1:100 does not show reduction of oxygen content below the initial content. (See Diagrams IV and VII; Results Series IIA, page 14; Results Series IIB, page 16.)

7. The average rate of absorption of oxygen by quiescent salt water may run as high as 0.306 c. c. per day, and of salt water moving at the rate of one foot per second, as high as 0.515 c. c. per day. (See Conclusions, Series IIB, page 16; Results, Series IIIA page 18).

4

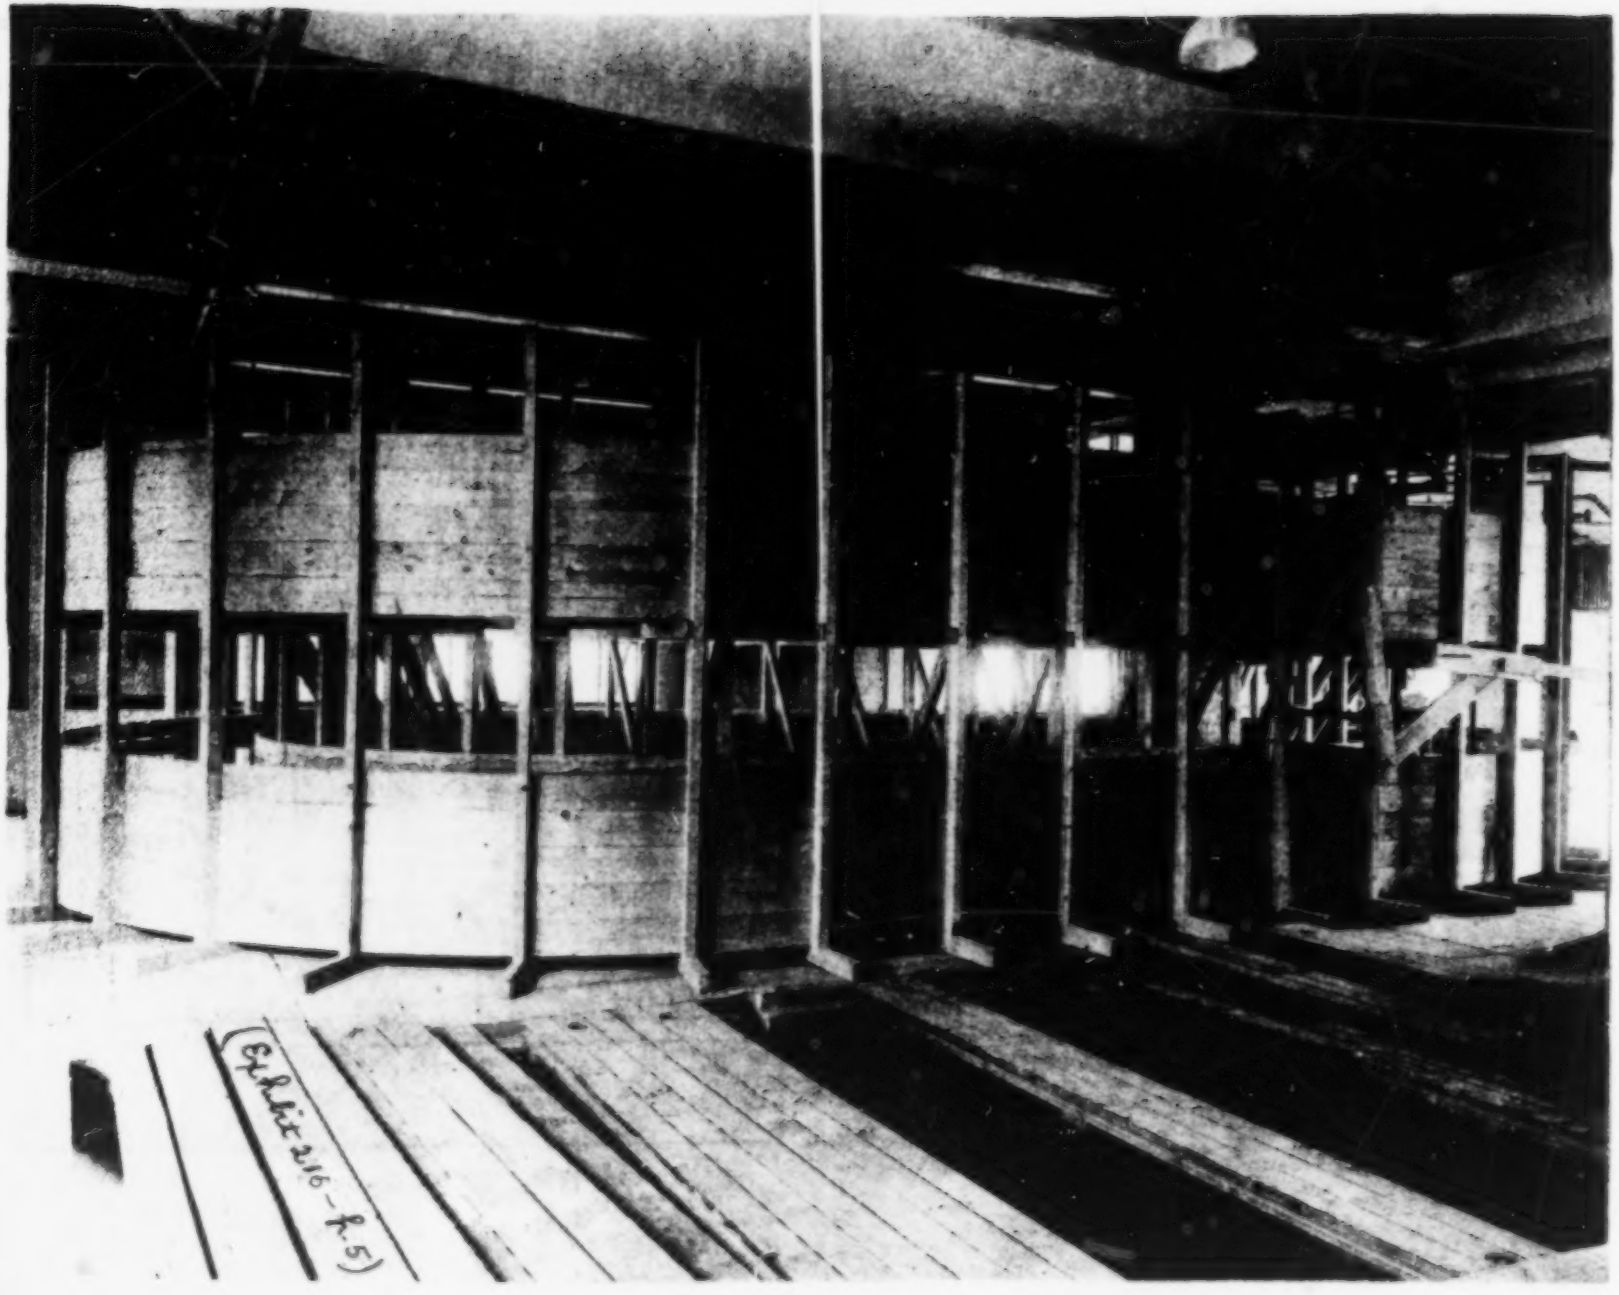
8. Salt water moving at the rate of one foot per second seems to be able to take care of sewage in the dilution of 1:60 and possible even the dilution of 1:30. (See Results, Series IIIB, page 20; Conclusions, Series IIIA, page 19.)

9. Salt water whose oxygen content has been reduced to 3 c. c. oxygen per liter (Eddy's Standard) if quiescent will not take care of sewage discharge into it at the rate of one gallon of sewage to 60 gallons of water, but seeme to be able to take care of the sewage discharged into it at the rate of one gallon of sewage to 100 gallons of water.

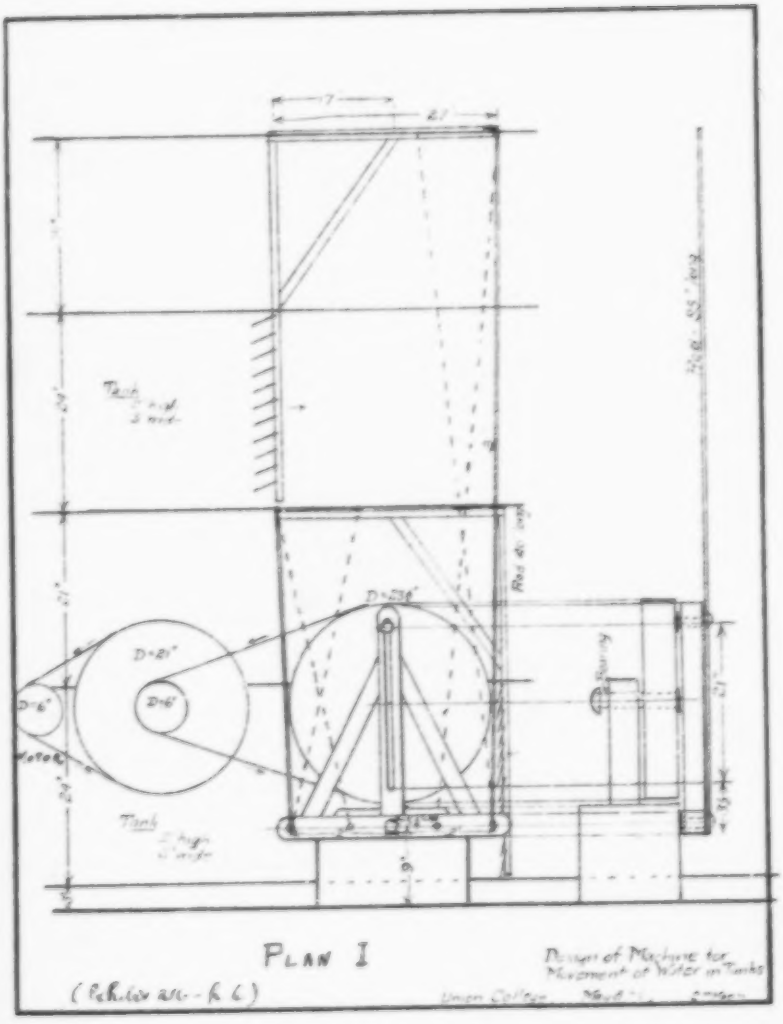
10. Moving salt water, containing 4.526 c. c. of oxygen per liter, seems to be able to take sewage in the proportion of 1:30 without diminution of oxygen content below 4.294 c. c.

11. The sewage disposal capacity of moving salt water seems large, if the sewage can be evenly distributed throughout its volume.

For this part of the study, waters were examined as follows:



I. Fresh and Salt Water.



II. Polluted and Unpolluted Quiescent Waters, with two degrees of pollution.

III. Polluted and Unpolluted Moving Waters, with two degrees of pollution.

This work involved a total of 700 oxygen determinations.

(Here follow two diagrams marked Exhibit 216, pages 5 and 6.)

Exhibit 216-F-5)

PLAN I

Design of Machine for Movement of Water in Tanks

(Parker and K C)

Union College

7 *The Apparatus.*

Two elliptical tanks, built one above the other as shown in the accompanying photograph, are used to contain the water under examination. The curved ends are semicircles of 7½ foot radius and the straight sides are 13 feet long. The width of the tanks is 3 feet and the depth of the water 2 feet. The cubical content of each tank is therefore 438.74 cubic feet, or 3,282 gallons.

The apparatus for keeping the water in motion, the levers of which are shown at the right of the photograph, was devised by Professor O. H. Landreth, to whom the grateful appreciation of the author is heartily given for his constant and valuable advice and supervision of the work. The details of the apparatus are shown in Plan I. Each tank is provided with a wing, extending across the entire width, which consists of a frame and shutters, so constructed that at the forward movement the shutters are closed, thus pushing the water ahead, and at the return movement are open, thus offering little resistance to the water. By swinging these wings backward and forward, the water is given a flowing motion around the tank, and, as the shutters are entirely immersed in the water, all aeration due to spattering is avoided.

Plan I also shows the propelling device. The wing of the upper tank is attached by a long arm to the right extremity of the "T", and that of the lower tank by a shorter arm to the left extremity of the "T". The "T" is provided with a slot in which the button
8 attached to the wheel moves up and down with each revolution of the wheel, thus giving the cross-arm of the "T" a motion similar to the walking beam of a steamer, and causing the wings to swing back and forth. The whole is attached by an intermediate shaft to a motor. The dotted lines in the plan show how, by attaching the rods at different places on the "T" and on the arms of the wings, different rates of velocity are obtained.

Owing to circumstances not under our control, the electric motor intended for use as a propelling power was not delivered at our laboratory in time to be available for this series of observations, and we were compelled to resort to hand power. This was placed at the end of the long lever shown in the photograph between the two tanks, and the wings were attached to each other by one long arm. The velocity of the water around the tank was measured at intervals, and it is believed the average thus obtained represents the real velocity of the water during the days on which observations on moving water were taken.

The object of having two tanks is obvious. With one containing salt water and the other fresh water, for instance, whatever the atmospheric conditions, both will be under the same conditions and subject alike to whatever change may take place in these conditions during any period of observation. As to the size of the tanks, it is our desire to study as large a volume of water as our facilities allow, and the apparatus was set up in the Hydraulic Laboratory of the General Engineering Building of Union College.

9 Humidity measurements were made by means of an improved form of Hygrodeik manufactured by the Taylor Instrument Company of Rochester, N. Y. It consists of two thermometers (wet and dry bulb) mounted on the outer edges of a chart, plotted from new and corrected tables prepared under the direction of the United States Weather Bureau.

Temperatures were read from accurate chemical thermometers, in Centigrade degrees. The thermometeres were suspended in and over the waters in each tank. For the convenience of those who are not accustomed to the Centigrade scale, the temperature readings are given in the tables as Fahrenheit degrees. It will be at once apparent from those readings that our experiments were conducted under summer conditions.

Atmospheric pressure was read from the ordinary mercury column barometer, graduated to give accurate readings to 1/100 of an inch.

10 *Methods of Operation.*

Each series of observations was begun by filling the tanks with water to within three or four inches of the top. When salt water was to be used, a measured quantity of salt was added. Live steam was led into the water until the temperature stood at about 60 degrees Centigrade. The valve controlling the steam jets is shown in the right of the photograph, just above the upper tank. The rate of absorption of oxygen by quiescent water is so slow that, by the time the water had cooled to room temperature, when observations were begun, a condition of 50% to 60% saturation was easily obtainable by this method. At the time of the last series, the college steam plant was not in operation, and advantage was taken in this case of the fact that the Schenectady water runs low in dissolved oxygen. It will be seen that that set of observations does not have so low a starting point as the previous ones.

Sewage for polluting the waters was taken from one of the manholes of the city sewers, just outside one of the entrances to the Union College grounds. Sewers come to this manhole from three directions, but all of them from residential portions of the city. The sewage used in these experiments was, therefore, entirely free from factory or trade wastes. Samples were collected between 7 A. M. and 8 A. M. in each instance, a period when the flow past this special manhole is larger than at any other hour of the day.

11 The method of determining dissolved oxygen used for these experiments was the so-called Lævy Method, which investigation in this laboratory in 1912 showed to be more dependable than other well known methods, when water contains a large amount of nitrites. The reagents are as follows:

Ferrous Sulfate:

144 grams Kohlbaum's crystallized ferrous sulfate, 15 c. c. concentrated sulfuric acid, and 3 liters of water.

Sodium Carbonate:

100 grams in 1 liter of water.

Sulfuric Acid:

Equal parts of concentrated acid and water Potassium Permanganate.

25.4 grams to 4½ liters of water.

This reagent was standardized against Sodium Oxalate obtained from the Bureau of Standards, Washington, D. C.

In place of the usual pipettes, burettes especially designed by this laboratory and made by Emil Greiner Company, New York, were used for measuring the reagents. The burettes were calibrated in accordance with the regulation of the United States Bureau of Standards.

The sampling bottles were of about 500 c. c. capacity, and three samples were taken for every determination, one for a blank and one for a check. The samples were drawn from "midstream" and at the middle depth. A siphon of small glass tubing was
12 used for the purpose, and was securely fastened in place in each tank, to insure a sample from the same point for each determination.

13 *Outline of Plan of Observation.*

I. A study of salt and fresh quiescent water.

II. A study of polluted and unpolluted quiescent salt water, with varying degrees of pollution.

III. A study of polluted and unpolluted, moving salt water with varying degrees of pollution.

Series I.

Comparison of Unpolluted, Quiescent Fresh and Salt Water.

For this series, the upper tank was filled with fresh water and the lower tank with the same water to which salt was added sufficient to give a salinity of 11,341.6 parts chlorine per million, or a little in excess of 60% of the salinity of sea water. The series ran through seven days, Sunday intervening, on which no determinations were made. The first day, samples were taken every hour, but the rate of absorption proved to be so slow that throughout the succeeding days samples were taken at intervals of three hours.

In this series as in all the others, air and water temperatures, humidity and barometer readings were taken with each sample. These readings are recorded in Table I. The curves for the amount of oxygen per liter are given in Diagram I, and a comparison of Oxygen and Humidity curves for both waters are given in Diagrams II and III.

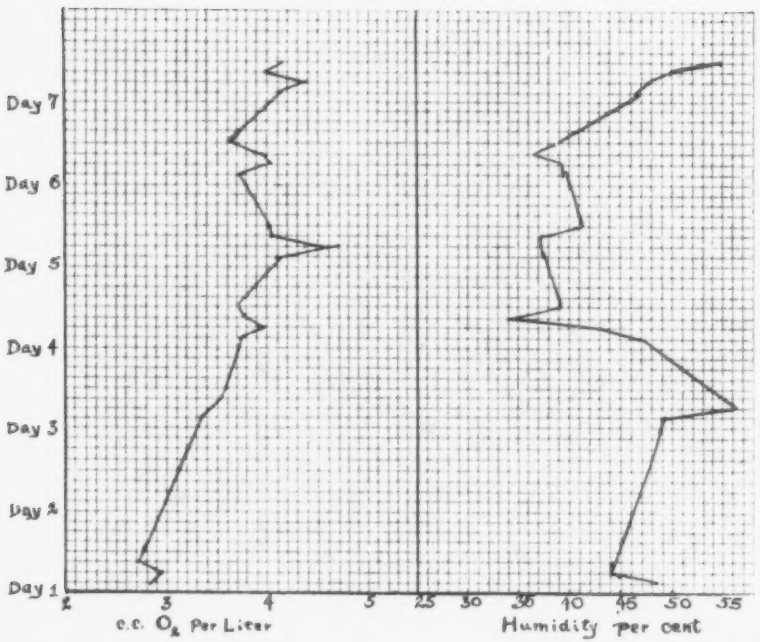
Salnity, 11,341.6 parts Chlorin per million.

(Here follow three diagrams marked Exhibit 216, pages 15, 16, 17.)

Diagram I.

Oxygen Curves, Fresh and Salt Water.

April 5-11, 1913.



(Exhibit No 216-A. 15)

Diagram II

Humidity and Oxygen Curves.

Fresh Water

April 5-11, 1913, inclusive

(Exhibit No 216, p. 16)

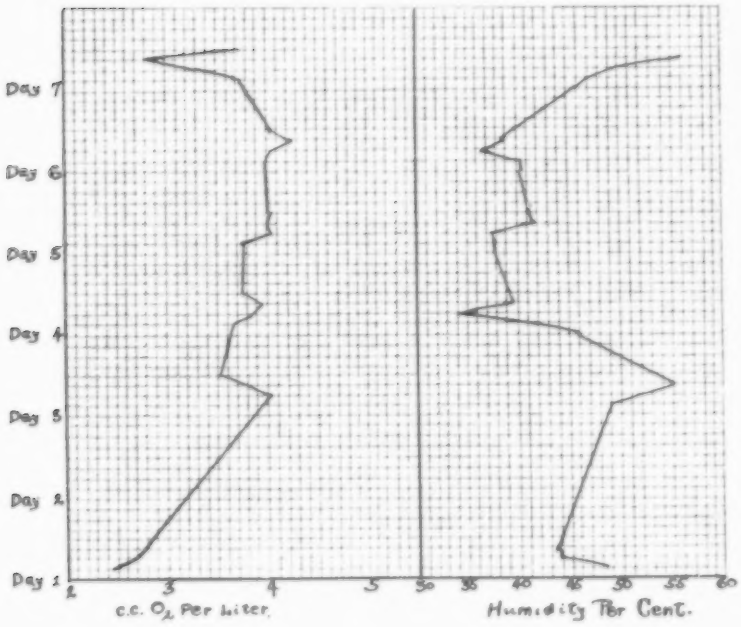


Diagram III

Humidity and Oxygen Curves.

Salt Water

11,341.6 parts chlorin per million

April 5-11, 1913, inclusive.

(Fr fisher Nr 216 & 17)

18 *Some of the Results.*

1. Increase of oxygen per liter from first reading of first day to last reading of last day,

Salt water..... 1.313 c. c.
Fresh water..... 1.303 c. c.

Average rate of increase per day,

Salt water..... 0.1877 c. c.
Fresh water..... 0.1861 c. c.

If sea water of this salinity, namely 11,341.6 parts Chlorine per million, i. e., approximately 61% sea water, contains at this temperature 5.9 c. c. oxygen per liter at saturation, and fresh water at this temperature contains 6.482 c. c. oxygen per liter at saturation, the above increase, in terms of per cent, is—

Salt Water, from 41% to 63%, total 22%.
Fresh Water, " 44% " 64%, " 20%.

2. Examination of Diagram I shows that, whatever may be the cause of the fluctuations, it affects both waters in the same way, for, in general, the curves break in the same direction. On these seven days, the changes of less than 1/10 of an inch in pressure and of about ½ degree Centigrade in temperature indicate practically constant conditions. But humidity changes are more perceptible, and reference to Diagrams II and III shows at four points, at least, that where humidity increased, on Day 1, Day 4, Day 5 and Day 6, oxygen content increased.

Some General Conclusions.

While salt water contains less oxygen at saturation than fresh water, both seem to absorb oxygen at the same rate, between
19 40% and 60% of saturation.

The absorption of oxygen by both fresh and salt water, is not so rapid as has been supposed, being in this instance about 0.18 c. c. per day, or about 3% of saturation value per day.

The effect of humidity is suggested by the results of the determinations; the greater the humidity, the less the absorption. Further investigation along this line will be carried out in this laboratory.

24 SERIES II.

Comparison of Polluted and Unpolluted Quiescent Salt Waters.

A.

For this series, the upper tank was filled with salt water, salinity 12,684.83 parts Chlorine per million, or approximately 68% sea water, and the lower tank with salt water, salinity 13,309.8 parts chlorine per million, or approximately 72% sea water. To the water in the lower tank, after cooling from heating, 55 gallons of sewage was added, giving approximately a proportion of sewage to water of one to sixty (1:60). Determinations of dissolved oxygen were begun immediately following the addition of the sewage, and samples were taken at three hour periods for five days. Readings are given in Table II and curves in Diagrams IV and V.

Some of the Results.

1. Increase of oxygen per liter from first reading of first day to last reading of last day,

Unpolluted Salt Water	1.226 c. c.
Polluted Salt Water	1.380 c. c.

Average rate of increase per day,

Unpolluted Salt Water	0.245 c. c.
Polluted Salt Water	0.276 c. c.

If the salt water of the salinity of the polluted water contains 5.68 c. c. oxygen per liter, at the temperature of this series, and salt water of the salinity of the unpolluted water contains 5.7 c. c. oxygen per liter at this temperature, the above increases in terms of per cent are—

25 Unpolluted Salt Water, 59% to 80%, total 21%.
Polluted Salt Water, 51% " 75%, " 24%.

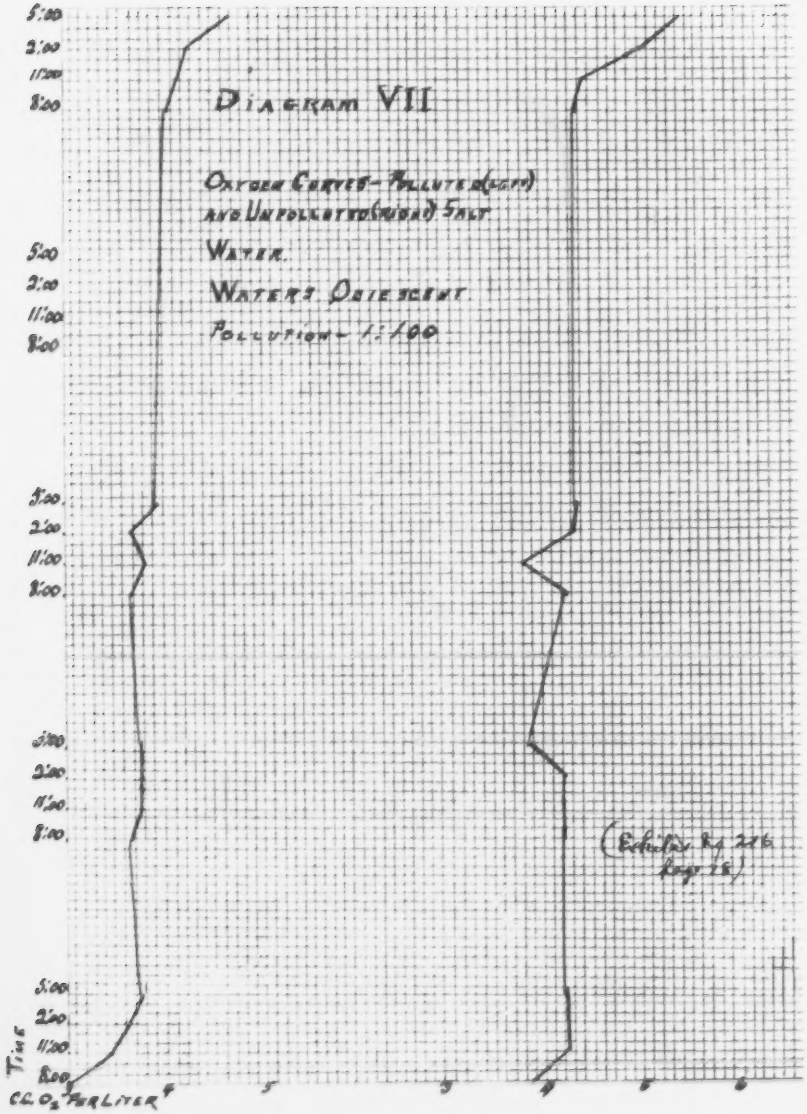
2. The curve given in Diagram IV shows that the first two days the curves diverge, the polluted water showing decreasing oxygen. Beginning at eight o'clock on the third day, and continuing two days, there is a steady increase of oxygen in both waters.

3. Comparison of the humidity and oxygen curves shows what Diagrams II and III show, namely, when humidity increases, oxygen decreases. The variations in any two successive readings of barometer and water temperature are very slight. This seems to indicate the effect of humidity.

4. The greater rate of absorption in this series as compared with

Series I is difficult to account for. The average humidity in both series is about the same, 43.6 in the first and 42.4 in the second. The barometric readings are approximately the same in the two series, and there is not a great deal of difference in the water temperatures on the Centigrade scale. The salinity varies a little, but the difference does not seem great enough to account for the greater rate of absorption.

Some General Conclusions.



The absorption of oxygen by salt water may under certain conditions reach the average rate of 0.276 c. c. per liter per day.

When quiescent salt water is polluted with sewage at a dilution of one to sixty, the first effect is a decrease of the oxygen
26 content, but after two days, the rate of absorption is quite as rapid as that of unpolluted salt water. It would seem then, that a dilution in this proportion is not permissible in quiescent salt water.

(Here follows diagram marked Exhibit No. 216, page 28.)

29

Series II.

Comparison of Polluted and Unpolluted Quiescent Salt Waters.

B.

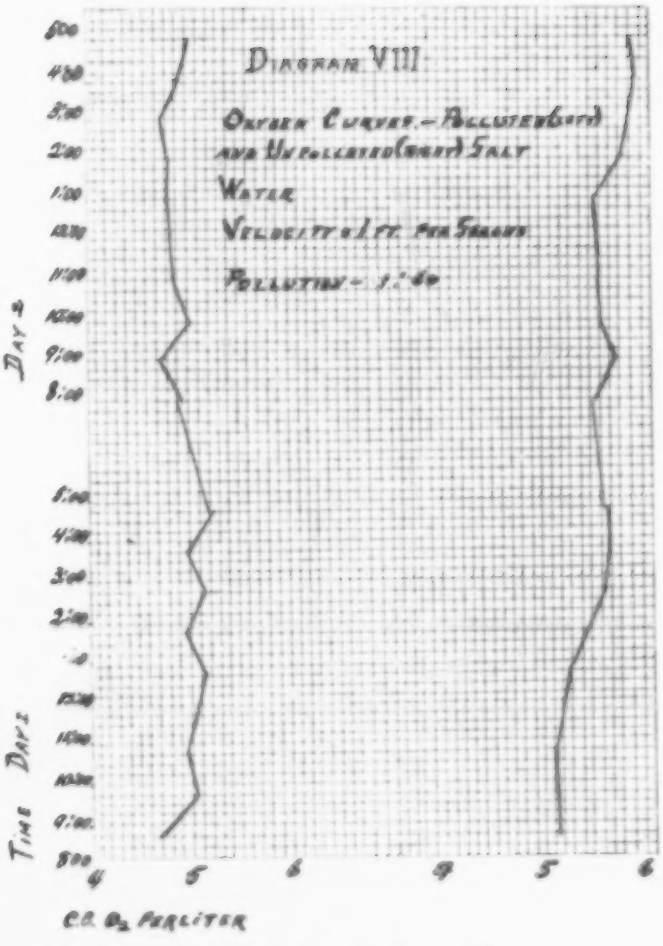
For this series, the upper tanks was filled with salt water, of the salinity of 13,610.7 parts Chlorine per million, approximately 73% sea water, and the lower tank with salt water of the salinity 11,897.8 parts Chlorine per million, or approximately 64% sea water. To the water in the lower tank, after cooling from heating, approximately 30 gallons of sewage was added, giving a dilution of one to one hundred. Dissolved oxygen content was determined immediately after the addition of the sewage, and at three hour periods thereafter for five days. The readings are given in Table III and the curves in Diagram VII.

Some of the Results.

1. Increase of oxygen content per liter from first reading of first day to last reading of last day,

Unpolluted Salt Water	1.533 c. c.
Polluted Salt Water	1.637 c. c.

Average rate of increase per day,



Unpolluted Salt Water	0.306 c. c.
Polluted Salt Water	0.327 c. c.

2. The curves given in Diagram VII show a very slight divergence after the first day and to the beginning of the third day. It would seem therefore, that a dilution of pollution of 1:100 was about what quiescent salt water of that salinity will stand.

30 3. If fluctuations are due to humidity, it is not so apparent in this series as in the first two. At one point in each of the five days, an increase in oxygen content was accompanied by a decrease in humidity; but at other points the oxygen content remained constant, or the change was in the same direction as the change in humidity.

Some General Conclusions.

The absorption of oxygen by quiescent salt water may, under certain conditions, reach the average of 0.306 c. c. per day. Quiescent salt water seems to be able to take care of pollution of one gallon of sewage to 100 gallons of salt water.

(Exhibit No 226, Page 32)

Salinity, polluted water, 13,240 parts chlorin per million.
Salinity, unpolluted water, 12,730 " " " "
Pollution, 1 gallon sewage to 60 gallons water.
Velocity, 1 foot per second.

(Here follows diagram marked Exhibit No. 216, page 32.)

33 SERIES III.

Comparison of Polluted and Unpolluted Salt Water in Motion.

A.

For this series the upper tank was filled with salt water, of the salinity 12,730 parts Chlorine per million, or approximately 68% sea water, and the lower tank was filled with salt water of the salinity of 13,340 parts Chlorine per million, or approximately 72% sea water. To the water in the lower tank approximately 55 gallons of sewage was added, giving a solution of approximately 1:60, the same dilution as in Series IIA, where the waters were quiescent. Oxygen and other determinations were begun immediately after the sewage was added, the water set in motion at a velocity of 1 foot per second, and determinations were made every hour. The readings are recorded in Table IV and the curves in Diagram VIII.

Some of the Results.

1. Increase in oxygen content per liter from beginning of first day to end of first day,

Unpolluted Salt Water	0.515 c. c.
Polluted Salt Water	0.523 c. c.

Increase in oxygen content per liter from beginning of second day to end of second day,

Unpolluted Salt Water	0.343 c. c.
Polluted Salt Water	0.174 c. c.

2. The curves show the general tendency to increase of oxygen content in both polluted and unpolluted waters, while the rate of both in the second day is less than the first, and that of the
34 polluted water much less, from the starting point of each day there is an increase toward the end of the day. During the night between the two days, when the waters were quiescent, the reduction in oxygen content of the polluted water was more marked than in the unpolluted water, but soon after the water began to move there was an increase in the oxygen content.

3. During the first day the humidity ranged from 48.5 in the morning to 36.0 in the afternoon, while during the second day it ranged from 59.5 in the morning to 62 in the evening, thus being greater on the second day, when the rate of absorption was less.

Some General Conclusions.

Unpolluted salt water moving at the rate of one foot per second, compared with quiescent, unpolluted salt water, shows rates of increase in oxygen content per day as follows:

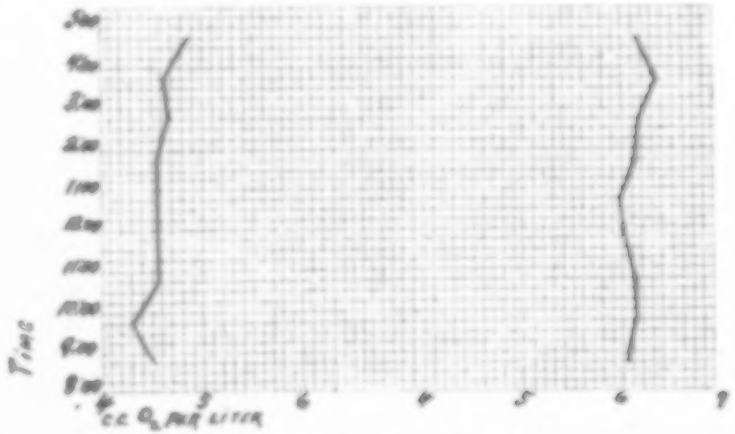

Diagram IX

Oxygen Curves - Polluted (left) and Unpolluted (right) Salt Water

Velocity 1 ft. per second

Pollution 1:30

(Unpolluted continuation of Diagram VIII)

(Rubner, p. 226)

Quiescent unpolluted salt water				0.245	Series IIA
"	"	"	"	0.306	" IIB
Moving	"	"	"	0.389	" IIIA

Polluted salt water, moving at the rate of one foot per second, compared with quiescent salt water of the same degree of pollution, namely 1:60, shows rates of increase per day as follows:

	First day.	Second day.
Quiescent, Polluted Salt Water	0.162 c. c.	no change
Moving Polluted Salt Water	0.523	0.174

It would therefore seem that a salt water moving at the rate of one foot per second could take care of more sewage than quiescent salt water.

37 SERIES III.

Comparison of Polluted and Unpolluted Salt Waters in Motion.

B.

For this series the upper tank was not changed, and the lower tank was filled with salt water of the salinity of 13,030 parts Chlorine per million and approximately 100 gallons of sewage were added. Oxygen and other readings were begun immediately and the water set in motion at the rate of one foot per second. The readings are given in Table V and the curves in Diagram IX.

Some of the Results.

Increase in oxygen content in one day, in the polluted water, is 0.348 c. c. Compared with the first day of other polluted salt waters, we get the following:

	Increase 1st day.
Quiescent, polluted salt waters (1:60)	0.162 c. c.
Moving " " " (1:60)	0.523 c. c.
" " " " (1:30)	0.348 c. c.

It would appear that moving salt water can take care of a large quantity of sewage, if the sewage can be evenly distributed through it.

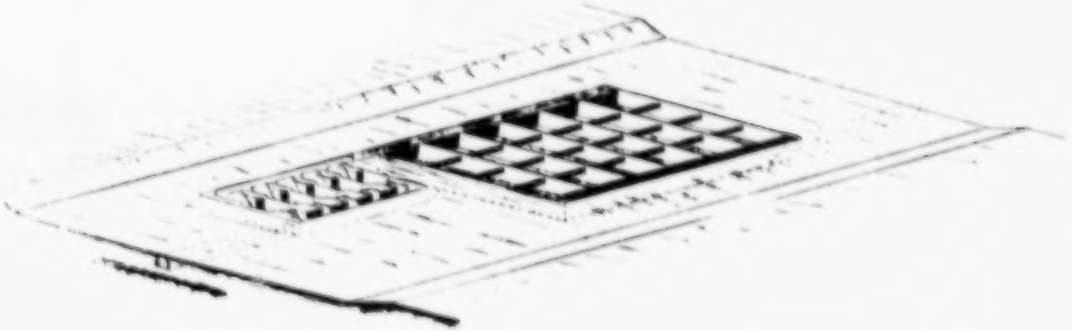
WAR DEPARTMENT
Standard Form No. 14.

5-1000

J. A. G. C.
(21290)

WHEREAS, In compliance with the requirements of a permit, dated May 11, 1910, THE PASSAIC VALLEY SEWERAGE COMMISSION (grantee therein) has now submitted to the Secretary of War, for his examination and approval, detailed plans of a sewer outlet and shaft house proposed to be constructed by said Commission in New York Bay; which plans have been recommended by the Chief of Engineers, United States Army, and as to which the DEPARTMENT OF COMMERCE AND LABOR will interpose no objections, provided the approval of said plans is given subject to the conditions hereinafter embodied:

NOW, THEREFORE, This is to certify that the Secretary of War hereby approves the plans for the said sewer outlet and shaft house, at said place, submitted as aforesaid; which said plans are shown on 60 blueprints marked "Ace No. B1000 - 1060", inclusive; and also bear the file number of the Office of the Chief of Engineers, United States Army "20103,111-170", and are referred to as a part of this permit.

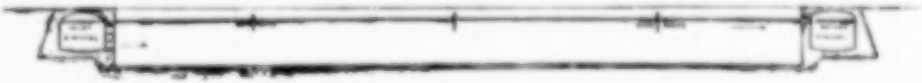


This approval is given subject to the following conditions and provisions.

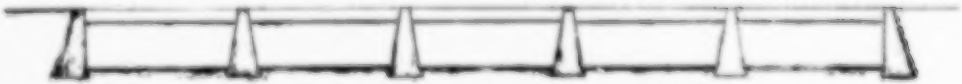
1.---That the conditions of the general permit of May 11, 1910, shall apply to the work herein approved.
2.---That for such details as are not yet determined upon, or are not sufficiently shown on said plans, further detailed plans shall be submitted for consideration when required by the district engineer officer.
3.---That no part of the terminal structure shall be less than 350 feet distant from the center of the Robbins Reef Light Station.
4.--That the terminal structure shall not be more than 40 feet high above mean low water.
5.---That the United States shall be reimbursed by the Passaic Valley Sewerage Commission for any expense to which it may be put on account of inspection of the works herein authorized.

WITNESS my hand this 22 day of SEPTEMBER, 1911.

Robert Shaw Oliver

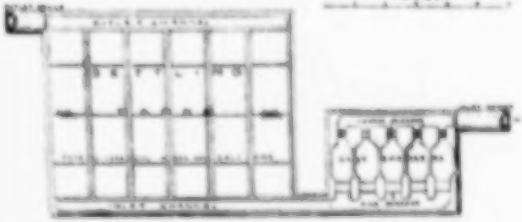


Acting Secretary of War.

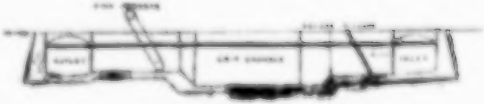


PASSAIC VALLEY SEWERAGE COMMISSIONERS

SCREENING APPARATUS AND SETTLING TANKS



NEWARK BAY PUMPING STATION



LONGITUDINAL SECTION THROUGH TANKS

TRANSVERSE SECTION THROUGH TANKS

GENERAL PLAN

SECTION THROUGH GRIT AND SEWER CHAMBERS

SCREENING APPARATUS AND SETTLING TANKS

Whereas, By Section 10 of an act of Congress, approved March 3, 1899, entitled "An act making appropriations for the construction, repair, and preservation of certain public works on rivers and harbors, and for other purposes," it is provided that it shall not be lawful to build or commence the building of any wharf, pier, dolphin, boom, weir, breakwater, bulkhead, jetty, or other structure in any port, roadstead, haven, harbor, canal, navigable river, or other water of the United States, outside established harbor lines, or where no harbor lines have been established, except on plans recommended by the Chief of Engineers and authorized by the Secretary of War; and it shall not be lawful to excavate or fill, or in any manner to alter or modify the course, location, condition, or capacity of, any port, roadstead, haven, harbor, canal, lake, harbor of refuge, or inclosure within the limits of any breakwater, or of the channel of any navigable water of the United States, unless the work has been recommended by the Chief of Engineers and authorized by the Secretary of War prior to beginning the same:

AND WHEREAS, THE PASSAIC VALLEY SEWERAGE COMMISSION has applied to the Secretary of War for permission to locate a sewer outlet with shaft house in NEW YORK BAY, in the vicinity of Robbins Reef Light, and to construct the necessary appurtenant works, in accordance with the attached agreement and plans, which have been approved by the Chief of Engineers, United States Army;

NOW, THEREFORE, This is to certify that the Secretary of War hereby gives permission unto the said THE PASSAIC VALLEY SEWERAGE COMMISSION to locate a sewer outlet with shaft house in NEW YORK BAY, in the vicinity of Robbins Reef Light, and to construct the necessary appurtenant works, in accordance with said agreement and plans; subject to the following conditions:

1.---That the work herein permitted to be done shall be subject to the supervision and approval of the Engineer Officer of the United States Army in charge of the locality.

2.---That if at any time in the future it shall be made to appear to the Secretary of War that the work herein authorized is an unreasonable obstruction to the free navigation of said waters, said licensee will be required, upon due notice from the Secretary of War, to remove or alter the same so as to render navigation through said waters reasonably free, easy, and unobstructed.

3.---That the tunnel under Newark Bay shall be constructed so as to give a clear depth of not less than thirty-five (35) feet at mean low water in the navigable channel.

4.---That the gate-house near Robbins Reef Light shall be erected at the point and under such plans as the Secretary of War, after consultation with the Secretary of the Department of Commerce and Labor, may hereafter approve; except as may be required in any particular by the terms of a stipulation or contract, of which a copy is hereto attached, made between the United States and the Passaic Valley Sewerage Commissioners under date April 14, 1910, whereby the parties to that stipulation or contract adjusted

the matters controverted between them in the suit of the People of the State of New York (United States, Intervenor) V. The State of New Jersey and Passaic Valley Sewerage Commissioners, being Number 6 on the Original Docket of the Supreme Court of the United States for the October Term, 1909.

5.---That the Passaic Valley Sewerage Commission shall remove from the waters of New York Harbor any shoals when the Secretary of War shall be satisfied that the same result from the discharge from the proposed tunnel and shall direct their removal.

6.---That all the terms and requirements of the divisions numbered First and Second of said stipulation or contract between the United States and the Passaic Valley Sewerage Commissioners, mentioned above, be at all times met and satisfied, according to the true intent of said contract.

IT IS UNDERSTOOD that this instrument simply gives permission under said Act of Congress to do the work herein authorized; that it does not give any property rights, and does not authorize any injury to private property or invasion of private rights.

WITNESS my hand and this 11 day of May, 1910.

Jno Dickinson

Secretary of War.

IN THE SUPREME COURT OF THE UNITED STATES.

October Term, 1 9 0 9.

THE PEOPLE OF THE STATE OF NEW YORK,

Complainants,) In Equity.

V.) No. 6 Original on the Docket for said October Term.

THE STATE OF NEW JERSEY AND PASSAIC VALLEY SEWERAGE COMMISSIONERS

Defendants.)

****

STIPULATION.

The United States having intervened in the above entitled suit with the consent of the court, and it being desired by the United States and the defendants in the suit to adjust the matters in controversy between them, in the manner and upon the terms and conditions hereinafter stated, and the State of New Jersey, by an act of its Legislature, approved on the eighth day of April, nineteen hundred and ten, having authorized the defendant, the Passaic Valley Sewerage Commissioners, to make this adjustment, IT IS NOW STIPULATED AND AGREED by and between the United States and the Passaic Valley Sewerage Commissioners, defendants in the suit, as follows:

First: The Passaic Valley Sewerage Commissioners agree with the United States that the sewer system to which the suit relates shall be constructed, maintained and operated if at all, in accordance with the following requirements:

(a) Upon the line of the trunk sewer and which it is proposed shall be constructed, and at a point at or near the

pumping station to be located on the Newark Meadows near the Newark Bay, it is stipulated and agreed that the sewage, waste and other matter passing through the said trunk sewer shall first pass through coarse screens to remove therefrom all large floating matter, and after passing through such coarse screens shall pass through a grit basin or basins where the heavy matter therein shall be taken out as far as practicable, from which basin or basins the sewage and other matter shall pass through self-cleansing mechanical screens having clear openings of not over 4/10 of an inch.

(b) As the sewage comes from the fine screens, it shall also pass through sedimentation basins. The sewage after passing through said grit basin and said self-cleansing mechanical screens shall enter the sedimentation basins or settling tanks consisting of a number of units, each approximately 225 feet long and 15 feet deep. Each tank will have a normal capacity of not less than 1,250,000 gallons, making an aggregate tank capacity sufficient to meet the requirements as stated herein. The tank capacity shall always be such as to provide a detention period of not less than one hour at the maximum rate of flow of the sewage and a detention period of the daily average flow of such sewage for not less than one hour and a half. The mean lineal velocities through said tanks shall not be over 0.5 inch per second for average flow, and 0.75 inch per second for the maximum flow. In addition to an in connection with these basins scum boards shall be provided to retain the floating matter, and proper and adequate devices shall be used to remove the retained scum and deposits from the settling basins; drawings of the general

plan of said settling tanks (sedimentation basins) as proposed at the outset being herewith attached as Appendix A.

(c) The sewage and waste thus screened and settled is then to flow into a pump well, whence it is to be pumped under pressure through a tunnel to a point in the New York Bay near Robbins Roof Light, at which point it is agreed that the matter passing through the said tunnel shall be dispersed into the waters of the New York Bay through a series of outlets discharging forty feet or more beneath the surface of the water at mean low tide. From the end of the tunnel connections shall be made with four or more discharge pipes extending across the current, spaced about one hundred feet apart, laid in trenches on the bottom of the Bay, and of a size decreasing in diameter from about six feet to two feet. On the top of these discharge pipes will be series of not less than one hundred and fifty tees of a diameter not exceeding one foot, and spaced approximately ten feet apart. On each of these vertical tees shall be placed outlets arranged to discharge horizontally across the tidal current, and the extent of the dispersion area used for this system of outlet pipes shall cover at least 3.5 acres of the bottom of the Bay.

Second. The Passaic Valley Sewerage Commissioners further agree with the United States that in the operation of said sewer system at all times the following results shall be secured, either through compliance with the requirements of the immediately preceding paragraphs, or through requisite lawful additional arrangements, viz:

(1) There will be absence in the New York Bay of visible suspended particles coming from the Passaic Vally Sewage.

(2) There will absence of deposits objectionable to the Secretary of War of the United States in the New York Bay coming from the Passaic Valley sewage.

(3) There will be absence in the New York Bay and its vicinity of odors due to the putrefaction of organic matters contained in the Passaic Valley sewage thus discharged.

(4) There will be a practical absence on the surface of New York Bay of any grease or color due to the discharge of the Passaic Valley sewage at the dispersion area of elsewhere.

(5) There will be no injurty to the public health which will be occasioned by the discharge from the said sewer in to the Bay of New York in the manner proposed and no public or private nuisance will be created thereby.

(6) The absence of injurious effect from said sewage discharge, upon the property of the United States situated in the Harbor of New York.

(7) The absence of reduction in the dissolved oxygen contents of the waters of New York Bay, resulting from the discharge of Passaic Valley sewage, to such an extent as to interfere with major fish life.

Third: The said Passaic Valley sewerage Commissioners further agree with the United States that so long as said sewer system, or any part thereof, is operated, the United States shall have, through such representatives as may be designated by the Secretary of War at any time for such purpose, full opportunity to inspect the condition and working of the sewer system, with a view to determining whether this contract is being in all respects performed, and that the said Passaic Valley Sewerage Commissioners will render such

expert or other assistance as the United States may desire in the course and in aid of such inspection and determination.

Fourth: The United States agrees with the Passaic Valley Sewerage Commissioners that forthwith upon the filing of this agreement, properly executed, in the office of the Clerk of the Supreme Court as a stipulation of the parties in the suit, it will discontinue its intervention in the above entitled suit and will cause its petition of intervention to be dismissed without prejudice, and will not again intervene in said suit.

Fifth: The United States and the Passaic Valley Sewerage Commissioners mutually agree, that this contract shall not become effective in any part, except the next succeeding divisions, unless or until all such permits as would be requisite under the statutes of the United States for the construction, maintenance or operation of said sewer system without this contract are actually obtained from the United States, or unless or until such permits are made conditional upon compliance at all times with all the terms and requirements of the divisions of this contract numbered First and Second, whether or not such permits contain other terms or conditions.

Sixth: The Passaic Valley Sewerage Commissioners hereby consent that full compliance at all times with the terms and requirements of the First and Second divisions of this contract be made express conditions of any permits issued by or on the part of the United States for construction, maintenance or operation of said sewer system, and agree with the United States that this contract shall establish such consent before all officers of the United States,

Seventh: It is agreed between the United States and the Passaic Valley Sewerage Commissioners that this contract shall bind and also shall enure to the benefit of the successors of the latter.

IN WITNESS WHEREOF this instrument has been executed in triplicate; being signed in the name and on behalf of the United States by the Attorney General of the United States and in the name and on behalf of the Passaic Valley Sewerage Commissioners by their president, and being sealed also on behalf of said Passaic Valley Sewerage Commissioners with their corportate seal attested by their secretary; all on the fourteenth day of April, Nineteen hundred and ten.

3 Arthur Sandford, Contractor, Newark, N. J.
Dr. C. T. Schondelmeier, representing the Broadway and Allied Press Trade, Brooklyn, N. Y.

The Chairman: Gentlemen, if you will come to order, I will state the objects of this hearing.
The hearing is called, subject to the following notice:

"United States Harbor Line Board for Harbor of New York and Adjacent Waters.

ARMY BUILDING,
NEW YORK CITY, November 14, 1908.

1. Under the Laws of the State of New Jersey, the Passaic Valley Sewerage Commission propose to intercept the sewage from the district now discharging into the Passaic River below the Great Falls at Paterson and the tributary district which may hereafter discharge into said river, and convey it beneath the waters of New York and Newark Bays by means of a trunk outlet sewer ending near Robbins Reef in Upper New York Bay.

2. Application has been made to the Secretary of War by the Passaic Valley Sewerage Commission for the consent of the War Department to the construction and maintenance of such sewer, and the matter has been referred to the U. S. Harbor Line Board for the Harbor of New York and its adjacent waters for a comprehensive report on this entire subject.

3. The Board will give a Public Hearing on this subject in the Army Building, No. 39 Whitehall Street, New York City, at 10 a. m. on Wednesday, December 9, 1908, which you are in-
4 vited to attend.

Very respectfully,

D. W. LOCKWOOD,
Colonel, Corps of Engineers, Senior Member of Board."

The Chairman: The original papers in this case are as follows:

"WASHINGTON, D. C., Oct. 6, 1908.

Hon. Luke E. Wright, Sec'ty of War.

DEAR SIR: I herewith hand you on behalf of my client, the Passaic Valley Sewerage Commissioners, application for consent of your department to the construction and maintenance of an outlet sewer beneath the waters of New York and Newark Bay, as fully described and shown by plans on said application.

As required by the regulations, I have also furnished two extra copies of the plan annexed to the application and also a copy of the opinions of Gener'l Henry M. Robert and other consulting Engineers on the matter as expressed in an official report made by the Commissioners to the Governor of the State of New Jersey, June 1903.

I shall be pleased to furnish the Department with any other available data desired in the proper consideration of this application.

Respectfully yours,

EDLOW W. HARRISON,
Engineer, Passaic Valley Sewerage Commission, Jersey City, N. J."

5 The Chairman: These papers were forwarded to the Harbor Line Board by the following endorsement: "War Department, Office of the Chief of Engineers, Washington, October 13, 1908.

1. Respectfully referred to Col. D. W. Lockwood, Corps of Engineers, for report by the New York Harbor Line Board.

2. It is the desire of the Chief of Engineers that in considering this subject the Board give consideration not only to the interests of navigation, but also to the interests for whose benefit this work is proposed. In other words, it is desired that the report of the Board cover the entire subject in comprehensive manner.

3. An expression of opinion is desired as to the practicability of requiring the builders of this sewage disposal system to remove by dredging any deposit in navigable waters caused by the projected works.

FREDERIC V. ABBOT,
Acting Chief of Engineers."

The Chairman: The application to the Secretary of War, upon which this hearing is based, is as follows:

To the Honorable Luke E. Wright, Secretary of War of the United States of America:

Respectfully represent the Passaic Valley Sewerage Commissioners acting under authority of Chapter 10 of the Laws of 1907 of the State of New Jersey entitled:

An act to provide for the purification of the waters of the Pas-

saic River within the Passaic Valley Sewerage District prohibiting the discharge of sewage or other polluting matter into said portion of said river after a fixed date, and authorizing municipalities
6 lying in whole or in part within the Passaic Valley Sewerage District, from the territory of which sewage or other polluting matter is or may be discharged into said portion of said river, to enter into contracts with each other and with the Passaic Valley Sewerage Commissioners for the intercepting and disposal of such sewage and other polluting matter, and to provide the necessary funds therefor.

Propose to intercept the sewage from the district now discharging into the Passaic River below the Great Falls at Paterson, and the tributary district which may hereafter discharge into said river, and by the course of said river and Newark Bay and Kill von Kull now reaches the Bay of New York; and convey said sewage by means of a trunk outlet sewer extending from Paterson to a point of discharge in the waters of New York Bay East of Robbins Reef at a depth of not less than 40 ft. below the mean high water in said Bay.

The proposed alignment and grade of said outlet sewer, from the Westerly side of Newark Bay to the outfall into New York Bay, are as shown on the map and profile attached, and may be further described as follows:

The sewer will be in tunnel from a point West of the Western shore-line of Newark Bay, passing under Newark Bay, the upland of Bergen Neck, and under New York Bay on a line passing as near as may be practicable to the Light House on Robbins Reef to a point where the tunnel intersects the rock contour of the bottom of New York Bay.

At no point in the line beneath the navigable waters of
7 the United States and outside of the established line for solid filling, will any part of such permanent structure, when completed, be less than 35 ft. below mean high water except upon the reef of rock North of and not more than 500 ft. from Robins Reef Lighthouse where it is proposed to place a permanent shaft and shaft-house, rising to a height not more than 20 ft. above mean high water.

The point designated for said permanent shaft on Robbins Reef will be preferably where the rock approaches nearest to the surface, and consequently beyond the limits of safe navigation.

The tunnel will have an inside diameter of 12 ft. At the Eastern end, where the rock contour is intersected, four or more pipes of cast iron or reinforced concrete of diameters varying from 6 to 2 ft. will be laid in trenches on the bottom of the Bay to such distances (within the limits of the State of New Jersey) in any direction as may be deemed necessary to procure a quick and free dispersion and mixture of the sewage with a large volume of Bay water.

The pipes will be provided with proper openings along their length so that the total volume of sewage discharge may be broken up in units of volume so small as to be quickly dispersed and diluted with a large volume of Bay water.

No discharge opening will be less than 40 ft. below mean high water.

The discharge of sewage through said sewer at present will be from a population of about 600,000 people or practically 10% of the total discharge of sewage into the Bay of New York from
8 the surrounding communities, including the territory to be served by the proposed sewer. The ultimate capacity of the sewer is computed to be for a population of 1,650,000 estimated to be reached in 1940, and it is contemplated will not at that time exceed the present proportion of 10% of the total sewerage tributary to New York Bay. It is proposed to subject the sewage to a process of thorough screening to remove matter carried in suspension, and also to provide for the sedimentation and removal of sand and grit, at the pumping station in the Newark Meadows, before allowing the sewage to enter the outfall tunnel.

The undersigned Commissioners respectfully request that the following works may be authorized, approved and permitted so far as they come within the jurisdiction and supervision of the War Department:

First. The construction and permanent maintenance of tunnels under navigable waters of Newark Bay and New York Bay, as shown by the plans attached.

Second. The construction, laying and permanent maintenance of four or more outlet pipes of a diameter varying from 6 ft. to 2 ft. in trenches beneath the navigable waters of New York Bay within the territory of the State of New Jersey, and not less than 40 ft. below the mean high water, as shown by the plans attached.

Third. Construction and permanent maintenance of a shart, and shart-house upon the rock of Robbins Reef not exceeding 100 ft. square, and not exceeding 20 ft. in height above high water.
9 The site of said shaft to be determined so as not to interfere with navigation, and not to be inconsistent with the proper uses of Robbins Reef for lighthouse purposes.

Fourth. The temporary erection and use, during construction, of such cribs as may be required for construction shafts in the navigable waters of Newark Bay and New York Bay West of Robbins Reef and outside the established lines for solid filling. The said construction to be located, built and maintained to the satisfaction of the United States authorities having supervision of said waters, and to be removed on the completion of construction.

Fifth. Permission to erect and maintain such temporary platforms, floats or other structures within navigable waters as may be required for the purpose of sounding and boring to determine the character of the bottom. The said structures to be located, built and maintained to the satisfaction of the United States authorities having supervision of said waters.

All work, in or below navigable waters, both permanent and

temporary, to be subject to the approval and supervision of the United States authority having jurisdiction over the said waters.

(Signed) J. A. LEBKUECHER,
FRANCIS CHILD,
W. S. A. KERMAN,
Passaic Valley Sewerage Commissioners.

Attest:
JOHN S. GIBSON, *Clerk.*

Dated, Newark, N. J., September 23, 1908."

10 The Chairman: The Board will listen to the parties in interest, in the following order: First, the applicants, the Passaic Valley Sewerage Commission; Second, others who favor the project; Third, the Metropolitan Sewerage Commission and the New York Board of Health; Fourth, the navigation interests, as to the effect of the work proposed, in possible deposits in the navigable waters in question; and, Fifth, the Attorney General of the State of New York, represented by Mr. Dean, attorney at law, on the subject of pollution,—respresentatives of organizations, and individual interests, with regard to the subject of pollution. It is desired that any one addressing the Board shall come forward and first state their names, and speak distinctly, so that the stenographer can hear them. It is also desired that, as far as possible, the various interests will be represented by but one speaker, if that can be done. The Board will now hear the applicants in this case.

Mr. Francis Child (Member of the Passaic Valley Sewerage Commission): Gentlemen, the duty of presenting the questions relating to the engineering features, and matters perchance of most moment, to you gentlemen, will devolve upon our Chief Engineer who from long association with the work, has become perfectly familiar with all its details. Speaking for the Commission, I have this to say:

The lamentable conditions of the Passaic River on account of its filth, have been such, and is such, that, for the last eleven years the subject of some feasible project for the cleansing of the River
11 has agitated the public mind. That the Passaic River is now, and has been for years past, little more than an open sewer, cannot be contested by any one, for the very simple reason that it requires only the olfactory sense of any person visiting that locality to discover that fact. The stench arising from the river is such that property lying along its banks, both on the East and West banks, or above, on the North or South banks, has been so seriously affected that its saleability has been almost destroyed, for factory purposes and, when used for factory purposes, as I myself have heard gentlemen at the head of those great manufacturing industries state again and again, that the stench arising from the river, particularly during the summer months, was so great that their employes, particularly the female employes—and there are a great many women employed in those various factories—was so seriously affected that many of them had abandoned the locality, and others

were seriously ill. These facts none can controvert; indeed, I understand, they are all admitted.

The water of the Passaic River is black; it is black with pollution. Owing to a peculiarity of the river, which may, or may not be known to you gentlemen, in its winding course, and in the tidal effect, a curious phenomenon takes place. The sewage which leaves the upper waters of the Passaic Valley Sewerage District, that is, at Paterson, as has been ascertained, occupy eleven days at times, sometimes even more than that, and other times less, before they are finally discharged from the river. This is owing to an oscillation, resulting from the winding character of the river, and the
12 action of the tidal currents. A little gain is made each day in the downward course of the sewage, which is only overcome to a certain extent, perhaps a large extent by the out-going tide, and then the sewage is driven back, so that, in this prism we have sewage of eleven days that has been confined there, oscillating backwards and forwards, and with the limited supply of fresh water mingling with it, this great mass of putrescent matter has been there for a period of ten or eleven days. Now, these are facts; there is no guesswork about it; it is the result of experiments. Every measure that could be suggested, offering any reasonable grounds of relief, has been investigated. Every thing, septic tanks, and all the modern improvements of science have been investigated and every one of them has been found unavailable. The reason of it is this: That we have in the Passaic Valley Sewerage District—we have twenty municipalities; you can see that, in order to establish a septic tank system one of two things would be necessary: Either the construction of a great intercepting or trunk sewer, which would gather the sewage at any and all places, and thereafter give the sewage septic treatment or such other treatment as research might show to be best. That is not feasible for the very simple reason that the ground for that work cannot be obtained. Individual municipal treatment is impossible for the same reason. I do not know whether you gentlemen are familiar or not with the locality embraced within the Passaic Valley Sewerage District, but you take, for instance, the
13 municipality after municipality that is so closely connected with the City of Newark, that when you leave the one, here, you can hardly tell when you enter the other, there, these municipalities being, in fact, practically suburbs of the City of Newark, and so it stands to reason that the only method left for us, the only thing we can discover after a research of over eleven years, and examinations and investigations by four successive boards or commissions, aided by the best engineering talent in the country—the only solution we can find, gentlemen, is the solution which is now proposed to you gentlemen, and which will be explained at length and, I trust, in a most satisfactory manner, by our Engineer, who is not only a good engineer, but has the advantage—from long association, of being perfectly familiar with this territory,—with the tidal action and other matters of great interest.

I would now merely call the attention of this Board to the fact that it is not the intention of the Passaic Valley Sewerage Commis-

sion to put into the Bay of New York one more—one additional drop of sewage. Everything which we propose to handle under this project is everything that goes into the Bay to-day, and has been going into the Bay since a time when the memory of man runneth not to the contrary. It has always been done. It goes in in the most offensive form; it goes in after being held back for a period varying from ten to more days. It is proposed—we propose to take this sewage,—remove from it all effluence which is objectionable to the eye; all that which floats,—all that which is offensive and
14 that which will offer any unsightly appearance in the water.

We propose to receive this in a large receptable—to lift it there by pumps and send it through a set of tunnels and then, after it reaches its outfall, after being completely screened and everything objectionable removed from it, nothing but liquid—then to discharge it—not from a twelve foot sewer—not from a twelve foot sewer—and you will see the plan which you have before you does not indicate any such thing as that—but to discharge it by means of as many separate pipes as may be necessary—to discharge it so that I think I can speak within reason, that unless—and this is proven by our own experiments—unless a person was informed of the fact that a sewer was discharging forty or more feet below the ground, they would not be conscious of its presence. That is all we say, and as we have reason to say, that this is the greatest reduction—as far as we can ascertain—that has ever been made in the question of sewage disposal. We discharge it through as many pipes as may be necessary, in deep water, distributed over a large area, after careful screening and sedimentation; what more can be done? That we conform to the requirements of the United States statute, of course, is known to you.

I will now present to you Mr. Edlow W. Harrison, and after he speaks, Mr. Rudolph Hering will be prepared to answer any questions which you gentlemen may suggest.

Mr. Harrison: Colonel, and Gentlemen of the Board, I will briefly state the engineering facts which we find are involved in this
15 question, and am prepared at the same time to state the bases of our conclusions as to the entire practicability and availability of the project, and will endeavor to answer such questions as you may desire to put, although Mr. Hering, who follows me, will answer all questions you may desire to ask in this connection.

First, I want to say a word or two, in a little more technical way, as to the methods by which this sewage now reaches the Bay of New York. The sewage which we propose to treat,—the sewage of the Passaic Valley, which is gathered from the towns on either side of that Valley, commencing with Paterson, at the foot of the Great Falls, down to the Southern boundary of Newark,—at Newark Bay.

The Passaic River, in the three or four months of the ordinary Summer of an ordinary year, running from perhaps the beginning of July, to the end of October, has a flow, a natural flow, of not over four hundred and twenty million gallons a day; rather less than that than more. The Passaic River, in an ordinary flood, has a flow of from seven thousand to eight thousand cubic feet per second, or from

five thousand to six thousand million gallons a day. Now, into this River, in the Summer months, with a flow of four hundred million gallons a day we throw the sewage from a population of some six hundred thousand people,—or about sixty million gallons, which is at the rate of a hundred gallons per head per day,—and I think it is right to use the standard of one hundred gallons per head, which is about the water use of the community. We throw sixty
16 million gallons of what I will call standard sewage. Standard sewage, in the ordinary American community—in some communities it is stronger and in some communities it is weaker than in other communities, but to take the average as a standard, the sewage of the Passaic Valley Sewerage District is no stronger per unit, and no weaker, compared to a similar standard, and we are ready to prove it.

The tide flow of the Passaic is weak during the four months of the Summer The tidal flow of the Passaic is peculiar during the four months of the Winter, or rainy season—the rainy months. The tide, coming in from the narrows of Newark Bay, meets the fresh water flow of the River from near its mouth; that is, the tidal prism, so to say, is filled with the fresh water from the upper stream, and rises, with the stream, to the salt water dam below. That is the condition during the rainy months.

In the Summer four months, the tidal flow of the River reaches practically to the village or City of Passaic ten or twelve miles above Newark and where the river is about six feet deep and four hundred to five hundred feet wide. A very small stream. Now, the river is narrow; the tidal prism is small, comparatively, to the amount of drainage drained on either side, and the amount of sewage coming in.

Now, during the Summer months, with the sixty million gallons total of sewage coming in, it takes, if a man may state it, from four to eleven days before the sewage deposited in the upper river reaches the Bay—Newark Bay. This accumulation starts after a
17 rain, and commences to accumulate, so that at the end of a dry period, there are some eleven days' sewage in the river, and an analysis of the river water shows that that is about the fact: That is, that the Passaic River, at the end of a dry period, from Market Street, Newark—that is at the Pennsylvania Railroad station in Newark, all the way up in its tidal course, to Passaic, which is about twelve miles, contains now, in the Summer months, somewhat more of a bacteriological population than the Chicago River did before the efforts were made and the work of constructing the drainage canal was instituted. Now, during that time the sludge deposit is deposited in the river; along come the Fall rains, when, instead of having four hundred million gallons a day, we have, in fact, water enough to fill the prism several times over, and as I have suggested, we have, I would say, from five thousand to six thousand million gallons per day coming down the river,—rushing down in freshet. That is so. This deposit is taken into Newark Bay and there deposited, and you gentlemen of the Harbor

Line Board know who takes it out; the United States has to pay to take it out and dredge the channel of Newark Bay.

Now, as I have stated, all of these facts prove the material effect upon the property on either side of this river; it has been reduced in value. As for manufacturing purposes, it is not sought for. The people who manufacture there don't want to stay, and new people do not come. All of the people who have come into that territory, all of the purchases that have been made in that
18 particular section of New Jersey in the last few years have been based on the idea that this Commission was hard at work and that a remedy would be evolved in a short time; otherwise they would never think of purchasing, never think of building in the Passaic Valley. I can speak of several industries who have done that, and they have gone there with the belief that, in a short time, the State having taken it up, by this Commission this sewage matter having been taken up, the remedy would be found.

Now, you see, that the effect of this is,—the fiscal effect, not only to destroy to a great extent the commercial and the business interests of the Passaic Valley, and its real estate interests as a place of residence and business, but it is also destroying Newark Bay. They are building up Newark Bay. They are filling up Newark Bay. They are making Newark Bay into a septic tank for the deposit of this sewage, and that is affecting the whole community of four hundred thousand or five hundred thousand more people in the City of Bayonne—in other counties, who are not in this district who are complaining and who are here to-day complaining,—represented here to-day.

Now, I want to speak of a matter in this connection, because it is properly brought before you, which is,—we hear often of how this question can be taken care of by some of the modern ideas in regard to septic treatment and filtration. Now, we have considered it. The engineers who have charge of the largest filtration works
19 in the United States,—the engineers who have charge of the largest sewage works in the United States, have gone into this subject; they have written about it; you have had pamphlets in regard to that,—they are not considered as part of our case here, but this subject has been fully considered.

In the first place, we have not been able to find a suburban community of this size, spread out as this is and as it will be in the next forty years, where success has been made of the local treatment of sewage. We have examined and looked into practically every sewage plant in all civilized communities both here and abroad, but we have not yet been able to find a plant which we would dare to place in the center of this suburban district, thickly populated as this is, within seven miles of the City of New York, and, finally, we have not been able to find any plant but what within a certain distance, from one-quarter of a mile to a mile, or within that radius, odors have not been found.

We have not been able to find in this community, in New York, Staten Island, New Jersey, or around the territory adjacent to the Hudson, any community which was willing to have a sewage dis-

posal plant within their territory, and I do not blame them. I don't blame any sensible man for not wishing to have it. This whole territory is building up; it is thickly populated, as are all other territories around New York City. In order to take care of this water—this sewage, our opinion is that it will require one thousand acres, and if it was all taken care of by one plant, which would be the sensible way, if that way was adopted, we should have to take out of the area of the City of Newark, one thousand acres. Now, Newark has about eleven thousand acres In the Southern district of Newark is the great manufacturing and commercial city. The meadows at Newark which, for many years, were looked on as almost valueless, are now very valuable. The developments in the Newark Meadows in the way of manufacturing interests now amounts to hundreds of thousands of dollars, I might say, millions a year, and the future developments are tremendous in their possibilities; they are increasing now rapidly, and the developments now looked forward to are generally now expected will amount to many millions more. And the potentialities of the Passaic Valley is that with the aid of the Government, and with what work has already been done under the direction of your Board, that this Newark Bay, this lower estuary—this lower Passaic, the estuary of the Passaic at Hackensack will become, as with Newark, a large commercial tributary of the port of New York and form part of the port of New York Harbor, and grow side by side, together with New York. Now, we could not spare at Newark, one thousand acres. We could not put up a set of sprinkling filters in the area of one thousand acres taken up by the residence and commercial land of the City of Newark, and, two miles away, is the best part of Jersey City, and with Southwest winds, Jersey City would get the benefit of the sprinkling filters, and with Southeast winds, the City of Newark would get the benefit of the sprinkling filters; and, another most important point, in my idea is, that you will not find a sewage disposal plant anywhere but what the flies are innumerable and insufferable, millions of flies, and, with our present knowledge of sanitary affairs, we know that enormous quantities of flies would be dangerous in the vicinity of a large population. The only City that has tried that on a large scale is Berlin, and Berlin has fifteen hundred acres of sandy land for her sewage disposal plant—they do things differently in Germany——

Col. Ruffner: Did you say fifteen thousand acres?

Mr. Harrison: Fifteen hundred acres; that is, one thousand acres near the city, and public lands in the vicinity—the public lands altogether amount to fifteen hundred acres of sewage farms in the vicinity of Berlin; that is the case with the City of Berlin, but in none of the great harbors of the world, they have not there the great rush of waters we have here; the City of Berlin is far from the sea, and there was nothing else to be done, and even there, no citizen of Berlin, not a scholar, would be proud of the sewage disposal works, but being to a large part established under the well-known economic policy there.

Now, to cure this evil, this Commission, after a thorough study and after a number of the brightest of all our engineers have determined that the best disposition was the natural, first, disposal, due to our situation and to our being part of the harbor of New York, and to the magnificent advantage which this whole metropolitan district has, with the large flow of water and plenty of it, to take care of this project with safety, we finally decided
22 that the only, best, most economical and also the method in the line of improvement, future improvement, was to follow out somewhat the Boston method, somewhat the London method, somewhat more the Boston method, and with improvements.

Now, we propose to take that sewage down to the shore of Newark Bay, and there pass it through screens and sediment chambers, settling chambers, and remove from the sewage the heavy grit, all the floating particles, and, as you will perceive by our specifications which you have before you, we do not say just how much will be removed; we say "all that is necessary or shall be necessary" shall be removed, so that there will be no danger of an offense arising in the outlet.

Now, there is no question that we can do that. The City of Hamburg does it, there, with a population of over one million. They pass the sewage through a house there, through a house with settling chambers—over screens—the City of Hamburg passes the sewage through screens, then out into a settling tank or chamber eighty feet wide by thirty feet deep, after it passes through this chamber it passes through six sediment tanks, thence into towboats, for the sediment, and then discharged into the middle of the river, and the whole river traffic of the City, the ferryboat traffic and general river traffic passes over it; the main ferry station crosses the river, and excursion boat traffic with a station right over in front of the pump house and wharves in front of the pump house, and the Hamburg-American Line docks, about a mile or two
23 below, are right in the track of this sewer, and you cannot tell there is any sewer in there at all. The River Elbe——

Col. Ruffner: What is the rise and fall of the tide there?

Mr. Harrison: They have a rise and fall of about eight or ten feet, the result being that in order to save pumping they made their sewer so large, with their tide locks, that for four hours each tide the sewage flows up inside and fills up this very large sewer, much larger than ordinary, and they have, from my own knowledge, a great advantage, in the rise and fall of the tide, over what we have on our low level—we do not think it a great advantage, but they do that because it saves pumping, and then the gates open automatically, as the tide goes down and the flow goes out, there has been an accumulation by the intercepting of the flow, causing the sewage to back up in the sewer, which was made larger for this very purpose, which results in this sewage being locked into the large main sewer during the flood tide, so that practically sixteen hours' stuff has to be cared for on the ebb. Our project proposes a very large improvement over this method, as they have to provide for the accumulation

and have made the sewer larger than ordinary for the purpose; while we, however, will not have to hold this tide locked sewage. We improve a great deal, I think, on that; they have a very coarse screen, and the Hamburg sewage is heavy, is very heavy, it is very strong, probably twice as strong as the sewage in the vicinity of New York or in any of our cities.

24 Now, there has been a great misapprehension as to the amount of sewage—or a great misunderstanding, at least, as to the amount we propose to put into this trunk outlet sewer.

Now, I want to say to the Commission that the people of the Passaic Valley are no different than the people of the City of New York, and they do not furnish any more sewage per head than the people of New York; and this mistake may have arisen from the fact that a figure has been used in our descriptions, and in all good faith, fixing the maximum capacity of the sewer at 360,000,000 gallons per day ultimately; that is the ultimate capacity of the sewer, built to take for four or five or six hours, the peak capacity, the peak of the quantity of stuff which must pass through it; you all realize that at certain times of the day the flow of the sewage is much greater than at other times of the day of twenty-four hours, as in every community the same rule answers; now this figure is fixed as the peak of the flow, the maximum capacity of the sewer, three hundred and sixty million gallons; but the average capacity of discharge to-day is nearly—the average maximum discharge is only about two-thirds of that, or two hundred and fifty million gallons, and that is a capacity or average which we estimate will be effective around 1940; that, in other words, is the ultimate capacity. That will include, under the law under which we are acting, the house sewerage, a certain amount of ground water which cannot possibly be kept out of the sewer, and not more than ten per cent. of the trade waste, and when I say trade waste, I mean the total effluence from factories, much of it being clear water; the idea being that the operat-

25 ing of this sewer in a separate system, which is required in all communities, at times, the factory waste will be treated, as it is being treated at the present time and particularly as treated in other communities, and reduced by this treatment so that ninety per cent. of the water will pass right into the river, which, of course, will not injure the river at all. I believe, from our investigation—there have been investigations made in Paterson, N. J., by Mr. Hazen, there is no trouble about doing this; there is no difficulty whatever to do this.

Now, the present discharge is seventy million gallons of sewage; the maximum will be two hundred and fifty million gallons, and not two hundred and fifty million gallons of standard sewage, because the standard sewage — that will be the sewage from about one million and a half of people and the standard sewage of one and a half millions people would not be over one and a half millions gallons, and an additional one hundred millions would be made up of a large amount of ground water, and it is very necessary that there should be a large allowance made, because the Eastward slope of the Orange

mountains is of gravelly formation and contains enormous quantities of underground water.

Now, after this sewage is pumped up, it is sedimented and passed through screens, passed through a settling chamber, and then we propose to send it through a twelve foot channel running under this head, under pressure, the top of the tunnel being thirty feet be-
26 low mean high water; now, when I say not less than thirty feet, I mean, if it should be determined that we will go some twenty-eight or thirty feet below mean high water, it will be in the rock bed, in case you want to dredge where I call the Jersey Flats, the Jersey City flats, it will be in the rock bed, and hence no interference with navigation——

Col. Ruffner: What will be the depth of the top part of the sewer below mean high water as it crosses the Bay down there?

Mr. Harrison: The top line of the sewer will be below the water line—will be at an elevation minus fifty feet below; it must be remember- that in addition the sewer is twelve feet, lying on the bed of the Bay, or if it have a range from twelve to fourteen feet at the outfall, we might say thirty-six feet below low water——

Col. Knight: Below low water?

Mr. Harrison: Below high water. The plan was based on the idea that the requirements would not be over thirty feet below high water in the rock bed in Newark Bay——

Col. Knight: In the Bay?

Mr. Harrison: Yes; in the Bay, and also on the Jersey Flats between Robbins Reef and the Jersey shore; the Pennsylvania dredge is about twenty-five feet, the foundation for the new Pennsylvania yards is about twenty-five to thirty feet. Now, we probably will put that down even lower; the question of whether that tunnel in place shall be minus fifty feet or minus sixty feet has very little bearing upon the case. We may be able to find the rock and
27 follow it throughout the Bay by going down a few feet more. What we look for is a way for the tunnel: if the course can be better had down ten feet below minus fifty, I do not think there will be involved much more expense for the shaft, allowing us to keep within the shaft,—there will only be required a little more pressure there with the air; if we have to use air; I don't expect to have to use air only for a very short distance there.

Now, when we bring that out to Robbins Reef, where, in the vicinity of the light house there is now about, by our chart, five or six feet of water at low water, that is nine or ten feet at high water; and there,—or about there (indicating on map) we ask you for a shaft, and we ask you for the right to establish a tank or gate house in which we can control the flow from the tunnel into the discharge pipes although it is probably not absolutely necessary that we should have that; but it would be better for the project, better for the United States Government, better for all interests that there should be something there where the flow of these pipes could be controlled, and in order that they could be controlled in the flow; we would then be able to throw a larger velocity through any one of the pipes or in all of

them for cleaning out and scouring; also, in case of a repair to a pipe, we would be able to shut it off there without going into diver work.

You already have an obstruction to navigation on that reef; a Light House; the Reef was deeded by the State of New Jersey
28 to the United States, during the administration of Governor McClellan and the United States holds it for light house purposes; the State reserved in the deed the right of reversion *it* case it should be abandoned for lighthouse purposes and any use for any other purposes.

Of course, the Commission acts under authority of the State, and have the right to the use of any such reversionary interest of the State or rights of the State in any way. Now, I am well aware, the Commission is well aware, that probably the question of the location of this building—this structure is a small, common structure, architecturally—as it is contemplated to put upon this rock as a shaft and pump house—we know that the question of its location there on that reservation does not, I believe lie with the War Department, but that the final location would probably lie, we understand, with the Department of Commerce and Labor and as that Department requires; but the question of obstruction comes to you; that is the reason we apply to the War Department,—in regard to the obstruction. Now, if the Department of Commerce and Labor don't see fit—we think it should be as near the light house as possible,—in fact, my own opinion is that if we put up a proper kind of a structure the upper part of it could be used for light-house purposes instead of the small light house there as it is—the light-house there now is forty feet above high water; but, if the Department of Commerce & Labor don't consider that a proper place to put it, three hundred and fifty feet from the light-house we are in the lands of the State of New Jersey, and, therefore, we ask you for the right to put
29 it there on the same reef, about the same height or elevation, about the same part of the rock—we ask a right to put our shaft there.

Now, from this shaft and from this gate-house, which is practically the end of the tunnel, we propose to extend into the distributing ground, a series of perhaps four, we will say, four hundred four foot pipes; they will be rivetted; they may be rivetted steel, may be cast iron,—but we are not determined yet what will be the best use. They will, of course, have flexible joints. They will be laid in a shallow trench on the bed of the Bay. They will extend out to a depth of forty feet where there is water forty feet deep, on a forty foot paral-el/ line vertically below high water, and there we will commence to allow the sewage to go out, and we propose then to diminish the pipes across the channel, or into the channel, all within the limits of the State of New Jersey, sloping the fall of the pipes from 40 to 60 or 70 feet, and we propose to have openings in these pipes, in the several pipes, perhaps fifty or sixty openings, or as many as may be necessary, and the pipes, with these openings, will be distributed over as large an area as necessary so that every part of this filtered sewage, as it comes out from the pipes, will almost immediately be diluted with a proper proportion of Bay

water in order that the sewage may be thoroughly dispersed and that there shall be no offensive conditions arising.

Col. Knight: Do I understand that those pipes that you say you will have come down a slope—when you speak about sloping,
30 do you mean that the pipes will slope downward from the mouth of the tunnel for the length of the pipes, which you say is to be about 400 feet?

Mr. Harrison: When I spoke of sloping down, I referred to having the pipes slope downward toward the bottom of the bay, from a depth of forty feet to a depth of perhaps seventy feet, depending on the depth of the water.

Col. Knight: You propose to continue the pipes down to a depth of seventy feet, on a slope?

Mr. Harrison: They will be put at a depth of forty feet, and slope downward, with the several openings so distributed as to secure the best results in dispersion.

Now we do not limit ourselves in our specifications as to the practical plans; we do not limit ourselves, nor in the contracts which will be made with the municipalities under the law to how much that area of distribution will be or how many pipes may be necessary or how many openings may be necessary; we say we will give as many openings and over as wide a distributing area so that the volume of water in the Bay, flowing from forty feet to seventy feet deep will be sufficient to dilute the sewage as quickly as it comes and we put it out in small units to mix it at once with the water of the Bay. There we get the ideal practice. We get a great volume of water in the New York Bay; the great trouble in all sewage systems is the need of mixing quickly the sewage with the diluting water,—the oxidizing water. Now, in regard to that thing,
31 I want to give a few figures which are the result of our investigation and on which we base part of our argument; we believe and we know that they are correct.

And, first, I want to remind the Commission that the standard of dilution for Chicago was one to twenty; one part of sewage to twenty parts of lake water passing through; that is the standard,—one to twenty, or one unit—or four cubic feet per second of flow for each one thousand people—the ratio of the diluting water as to the population for the sewage——

Col. Knight: One moment; is the character of the Chicago sewage that you are going to refer to now, of the same character as will come from your effluence there?

Mr. Harrison: Well, leaving out the stock yards sewage, the character of the Chicago sewage is much stronger, as much of it is not screened——

Col. Knight: That is what I wanted to develop.

Mr. Harrison: Let me say, in regard to the screening proposed,—from the very best authorities, when we have screened sewage and when we have deposited we have thus reduced its pollution—its powers of pollution—power of offense so that the oxygen required to entirely destroy it is fifty-eight per cent of the normal; that is, if it takes one hundred per cent. of oxygen—that quantity of oxygen to

destroy the power of pollution of ordinary sewage, screened sewage, in the way we propose to put it through, as sedimented sewage, it is about 58 or 58 and a half—fifty-eight and a half per cent. of
32 oxygen will do it; that is, we practically take out about forty per cent of the putrifying substance. I give that on the authority of the English Royal Commission, Hall and Gibson, authorities on the subject.

Now, we will say that Chicago is as one to twenty;—Milwaukee is one to twenty-six,—in the improvement of the Milwaukee River. In the English Royal Commission, the result of their experiments show, as applied to American sewage, that it seems to be that the dilution of one part of sewage with fifty parts of ocean water—Bay water—salt water—sea water—one to fifty, with absolutely no knowledge whatever that anything was being put into the water—I mean that the sewage may be taken care of with no knowledge to the senses or to the observation that it was going into the water at all. I only give this as a sort of measure or scale by which to figure the figures we propose to give further on.

Now, from experiments we have made, only one or two, one which I happened to have right at my hand last night, an experiment made at ebb tide at Robbins Reef, in the Summer; we found at the surface eighty-eight and five-tenths per cent. of the normal quantity of oxygen in the Bay; that is, that the pollution first of the whole of New York, the whole of New York island, the City of New York, the pollution coming through the Kills and mingling with the waters of the Bay had not cut that oxygen down only eleven and a half per cent. Now the authorities are all agreed that water, as long as the oxygen is not cut more than fifty per cent. the sewage can be put into the river water
33 without offence to be taken care of. Of course, I am not making that as a statement of fact. I do not want to go too deep into this thing; I am only stating points upon which we base things. Now we find—at a point, you asked me in regard to the constituents of sewage. The speaker is asked for a comprehensive view of this. Perhaps I am going further than should be done, after having stated to you, and I am willing to prove it, that the sewage will be liquid; we propose to discharge liquid sewage into New York Bay; sedimented and screened, and under section 1307 of the River and Harbor Law, liquid sewage seems to be separated from the interdicted articles which are there legislated against being thrown into the bay or into United States waters.

Now, there is a question raised that the sewage of the Passaic Valley is particularly bad. That there is something in the sewage of the Passaic Valley, it has been alleged, different from other sewage; something that will rot timber, and tear out the bottoms of ships and things of that kind. Now, these are the facts, and these, presumably, because they are so manifest on the Passaic. Now, the facts are these: The population of the Passaic Valley as compared with the population of the rest of the district draining into New York Bay is as one to seven and six-tenths.

Col. Knight: One to seven and six-tenths?

Mr. Harrison: Yes; to the population of the one, the population of the other sections in this district is as one to seven and six-tenths.

Now, the manufacturing establishments liable to pollute the
34 streams, I have taken from the United States Census; the manufacturing establishments which are considered by scientific men—sanitary men—as those of a class which furnish large amounts of waste or polluting waste such as breweries, silk mills, dyeing establishments, leather tanning industries—I can give the whole list if necessary—any sanitary man would be able to pick those out at once himself,—they are in the ratio of one to sixteen as to number,—that is, for sixteen of such establishments in the territory including Hudson County, Jersey City, Hoboken and districts draining into New York Bay, direct, to one establishment on the Passaic. The capitalization is as one to seven; that is, our establishments are larger. The labor is as one to four. That is, we employ somewhat more labor. The value of the product is as one to seven; that is, the capitalization and the value of the product are practically the same—the product and the capitalization; the population, the labor, is a little heavier, we need a little larger number of laborers to an establishment in the Passaic Valley. The number of establishments are greater in New York, Brooklyn and the districts around the Bay, directly draining into the Bay, and there is nothing in that to bear out the idea that there should be any difference at all in the sewage. Now, those are the figures,—the statistics in regard to it.

Now, when we come to an examination of the sewage, and we have had hundreds of examinations of the Passaic River, and there has never been an examination which resulted in finding
35 anything different in Passaic sewage from the ordinary sewage of American cities, or New York, or the ordinary communities around here, except this, it is darker and it is thicker because our diluting water is so little. It goes into a stream of very little water. If you take a white boat up the Passaic River in Summer and you will probably have a black boat when you come back, but that can be cured by dilution.

Now, the next point in regard to that sewage, we propose,—the methods we propose are so very far in advance of anything that it is away and beyond anything that is being done now. You have this sewage, as the Jersey side of it comes off the Kills now. There is practically nothing comes down Arthur Kill; the current is down the Narrows into New York Bay.

Now, I had an analysis made of the waters of the Newark Bay on October 23rd of this last year; that was the end of the dry period—the waters of Newark Bay at the Central Railroad drawbridge, near Bergen Point, in the channel there, in the swiftest part of the channel, at ebb tide, towards the end of the ebb; the samples were taken and the analysis was made by Professor Stillman of Stevens Institute, and showed Free Ammonia seventy-seven-one-hundredths parts in a million; Albumenoid Ammonia seventy-four-hundredths parts in a million. The analysis of the Ammonia in New York Bay as made by the Pollution Commission of 1904 and

others made by the Commission on a New Water Supply for New York, showed the average of Free Ammonia, commencing at Pier One and running down in New York Bay as one hundred
36 and twenty-nine-thousandths of a million, and of the Albumenoid Ammonia, one hundred and forty-three-thousandths of a million. That is, on October 23rd, of this year, after this dry period, the result of the accumulation of sewage in the Passaic River and Newark Bay has made the discharge of waters of and from Newark Bay into New York Bay contain over six times a greater quantity of ammonia and amount of sewage than the normal waters of New York Bay. That is, the water that is going in now, from Newark Bay—going in *in* the *the* Summer—not now, because we have had rain,—the water that comes into the Bay in the end of the Summer from the Passaic River into New York Bay has nearly four, five or six times higher standard than the waters of New York Bay as determined by the Pollution Commission, and our figures, as determined by this Commission, and I must say the facts since ascertained seem to bear them out. That is, when the waters of the Passaic River, by way of the Newark Bay, strike New York Bay, it immediately reduces the conditions of New York Bay, and the reason for it is that that four or five or six times higher standard of ammonias which is accumulated coming down to the Bay shows its effect on the normal waters of the Bay, and notwithstanding this was the condition there through, a simple analysis it is indicated what an enormous purification is shown, and it shows that even lying there in that dry period, and without getting the benefit of that dilution which the volume of water in New York Bay provides, simply from purification, septic tank action, still when it got through from the Passaic through the Narrows, it has
37 twice—it has, not twice,—it has as much, ammonia per unit in Newark Bay as there is in New York Bay.

Now, that brings me to the condition of New York Bay as we take it: We find—the Chicago River standard—in purifying the Chicago River canal, the ammonias are due to that admixture, would be six hundred and ninety-seven-thousandths parts in a million of Free Ammonia, and one hundred and thirty-nine-thousandths parts in a million of Albumenoid Ammonia, that is, fresh, just as it comes in—of course, Free Ammonia passes into Albumenoid Ammonia in time. By this Chicago River standard, the Newark Bay had more free ammonia on October 23rd than the Chicago River has, purified. That is, Newark Bay has passed the line of four cubic feet per thousand. When it goes to the condition of fifty per cent. free ammonia, it will begin to give out an odor and may become a nuisance.

Newark Bay, away down to Bergen Point, with the pollution passing down to New York Bay, in only normally polluted by all the sewage of New York, one-fifth the Lake Michigan standard,—the standard of the Chicago River: That is, New York now, taking the sewage into it of five or six million people could take five or six times as much sewage, properly diluted, properly spread and properly brought into contact with the waters of the Bay, could take

five or six times the pollution it now receives before it reaches what every engineer in the United States pronounced the proper thing to be the best thing, for the City of Chicago, and also pronounced the most capable of taking care of the Chicago River so that
38 there should not be a nuisance arise. There, the point is this: We propose to put only one day's supply into the Bay. Each day by itself, that supply can be reduced,—of putrescent matter somewhere around forty percent. No more. Nothing to make a deposit. A liquid. We propose to deliver it over such an area that just as soon as it leaves the pipes it immediately comes in contact with a flow, of water in the large prism above, and in regard to that flow, of the tide in the prism, taking the map as it shows there (indicating), and allowing the sewage in there to be going out, as spread out at about an angle of sixty degrees and coming up like smoke, the water of that prism, moving along at the rate of one and five-tenths feet per second, which is about the average tidal flow in New York Bay,—the mean of the tidal flow, the tidal flow in that prism per second is sixty-three thousand cubic feet per second; that is, the prism above or across these pipes, flows at the rate of 63,000 cubic feet per second, and the discharge from the pipes,—the ultimate discharge, in 1940, our discharge then is two hundred and twenty-five feet per second,—the present discharge of it if in operation to-day would be one hundred and five cubic feet per second now, with sixty-three thousand cubic feet of tidal water per second to receive it.

One other point I want to make, and then I am through: The tidal volume, on the flood, in New York Bay, is said to be twelve thousand seven hundred and four million cubic feet, or about five hundred and ninety thousand cubic feet per second,— in six hours, twelve thousand, seven hundred and four thousand million
39 cubic feet in six hours, one flood. There has been a considerable discussion as to how much of that is sea water. Now, the New York Pollution Commission here referred to—they say they could not find it—now, I will ask them to look at their own report. They made a very careful examination and reported on the subject—that the bacteriological tests at a number of piers, commencing at pier No. 1, of the Iron Steamboat Company and going down to the Iron Pier at Coney Island—they started, the Commission started at the last hour of the ebb, on June 11th, presumably a warm day; they took bacteria tests at Pier No. 1, opposite Robbins Reef, Liberty Island, Gravesend Bay and in the Narrows. The report of the Board or Commission, in the first document they state they stayed there during the day and came back on the end of the flood, the last hour of the flood, in the afternoon. They took the same test of samples. The report of the Commission shows (Mr. Harrison is here referring piece-meal to the papers). The report of the Commission shows that they brought back fourteen and a half tests (they note the one-half test)—the report of the Commission shows they came back on the flood and they found one-half of the bacteria—just about one-third to one-half the quantity of

bacteria from the samples that they found when they went out on the ebb.

Now, during that day, they were away when New York Bay was tide-locked—they went down the last hour of the ebb, before the flood had closed the sewerage in—during the time it was tide-locked—the sewerage went out, one-sixth of the total
40 sewage in New York Bay, going into the Bay, bearing in it million of bacteria, the afternoon a warm one, in June, and the records of the Commission show that the water they took up was clear, clear, without stench, with practically plenty of oxygen in it; there was, also, a certain amount of Albumenoid Ammonia and Free Ammonia—(Referring to book—report—in making these remarks). That is all there (indicating)—increase in bacteria—whole afternoon—increase coming back—found only one-half the bacteria they found in the morning—at the end of the flood—all the day the bacteria had been pouring into the river and Bay from the sewers, and nothing going out.

What is the answer? What is the best answer, with one-half of a flood tide, at least, coming up? I submit that the tide that comes up is ocean water; there is no other change—one-half ocean water—I place no significance in the quantity of bacteria. Now, we will take the bacteria as so much aniline dye found here, let us suppose that they went out and placed a certain amount of color in the water, distributed in New York Bay at the end of the ebb tide, and came back, and found one-half, on the end of the flood tide. What is the fact? The clean ocean water came in up there, dispersing the color, cleansing the source.

They say their figures there were surface indications: They know well that under the surface of the water there is double the amount of salt water at a level of forty feet below the surface of the river, say at 39th Street, where, below the surface, and again at 44th Street,
41 at about 40 feet down, we have found twice as much salt water as at the surface. This water at the surface contains more of the albumenoid ammonia, more of the factory waste, more of the fresh water, while below the surface there is less factory waste and a larger amount of ocean water; fifty per cent. of that water, at least, which came in on the flood tide into New York Harbor, is ocean water.

Looking over the report, you will find no difference in the albumenoid ammonia, practically no difference over several years; you will find no difference whether ebb or flood; you will find very little difference in the bacteria found, or a reduction; and still the whole thing is, that the standard,—the standard of purity of New York Harbor, the standard and measure of what New York Harbor can do to sewage, it means that New York Harbor can now, and is now taking care of a population of six million, with a result in impurities, in the suspended impurities, of about one-fifth the standard which is accepted by all engineers and all sanitarians throughout the world as being perfectly safe. That is the standard, day and night, Winter and Summer. It may in Summer work do somewhat, but not in Winter. In their report (Referring again to papers) they

have shown some figures, that is that for four or five months of the year these waters draining into New York Harbor, and found in New York Harbor, have as much as thirteen-hundredths of a part to the million of ammonia. The standard which is safe runs up as high as seven and three-tenths of a part to the million. Chicago can go along with seven-tenths of a part to the million of free ammonia and a nuisance will not arise. In New York Harbor
42 the extreme has been thirteen-hundredths part to the million as compared with the germ condition incident to seven-tenths part to the million of free ammonia in Chicago, and this extreme in New York is taken from the surface of the water. If you will take all of the sewage in New York out of the pier end sewers, and take out of it all the matter in suspension, and put it into a liquid form, and bring the sewage right up through the water from the bottom, making an admixture all the way through, that condition will not be found. The trouble with New York is they should adopt this plan, we believe, of screening and sedimenting of the sewage, putting only liquid sewage in, and putting it in at the bottom, out of pipes with a large number of openings, so that the water, coming in contact with the liquid will quickly disperse it. If that plan is adopted and carried out for the whole city of New York, the Bay will take care of the sewage of forty or fifty million people, according to the engineers, who practically agree on that question.

Col. Knight: The application of your Commission before the Board now involves the question of sedimentation?

Mr. Harrison: It does.

Col. Knight: And of screening?

Mr. Harrison: It does.

Col. Knight: There is nothing before the Board to show how you propose to do that, nothing to show what your interpretation is of "such screening as may be necessary". Are you prepared to give us more details?
43 Mr. Harrison: I will leave that question to Mr. Hering.

Col. Knight: It will be adequately determined?

Mr. Harrison: Mr. Hering will answer you in respect to that.

Mr. Dean: I would like to ask some questions of the speakers, and would ask whether you consider it more convenient for me to ask them as each speaker concludes his remarks?

The Chairman: You will be allowed to question them at the end of the presentation of the petitioners' case.

Mr. Dean: I would like to have the petitioners state here certain information concerning the sedimentation and screening which is not set forth in their specifications and which we have been unable to obtain.

Col. Knight: I think it would make the matter briefer to have the questions come at the end.

Mr. Hering: I propose to be brief and merely refer to some of the essential matters in this proposition.

Some years ago, I was first brought into contact with this proposition by the State Sewerage Commission of New Jersey who had then under consideration the purification of the Passaic

River; and there were presented to the Commission of which I was a member, a number of plans contemplating the purification of the sewage of the different municipalities. We considered those reports and plans and propositions very carefully and we came to the
44 conclusion that in our opinion none of them would answer the purpose for the future, and we could not recommend any of them. So, then, the question was, what shall we recommend? and, after consultation, we made a new proposition to the State Sewerage Commission, and recommended the disposition of the sewage of the entire Passaic Valley, in a proper manner, into New York Bay near Robbins Reef, where the present Passaic Valley Sewerage Commission proposes to discharge the same.

At that time the methods of sewage purification had not developed as far as they have developed to-day; in fact, they have not reached perfection yet, and I think—having been myself three years ago in Europe, and this last Summer in Europe, where they are ahead of us in this particular branch of engineering.

We found that not only the expense of the individual purification schemes would be great, but we were afraid that as this population grew, it would encroach upon the territory which, unquestionably, is more or less offensive according to all methods that we have to-day, unless you provide a free territory around the same so that we felt that we had to give a positive recommendation, and I mentioned it.

Now, then, the question was to satisfy ourselves that that was the right thing to do, and that it was better than any of the other propositions that had been made. I had the honor again to be connected with this matter, as one of the engineers of the present commission, and had the instructions to revise the entire question as if
45 it was a new one, and see what could be done. That was particularly proper in view of the fact that the methods of sewage purification had unfolded and developed, and that the conclusion had was better than seven or ten years ago. Another study was made very carefully, and I also examined personally the various works in the world, Europe and here, with some of which I am connected,—and, again, the same conclusion was reached.

Even those modern methods of sewage purification, which are much cheaper than former methods and can be controlled better, and do not require so much territory set aside for them, have figured out more expensive than the present proposition and, in addition to that, they practically set aside an area, I believe, of about one hundred acres, or something like that, somewhere in the Newark Meadows, being the only available territory left for sewage purification,—set aside that territory, and it will never be an assurance, from our present knowledge, that it will not be objectionable within a certain radius around the Passaic.

Our provisional thought was that possibly a quarter of a square mile would practically have to be devoted to the project, or a reservation of perhaps more territory. These calculations were made on the very latest and best experience in Europe. We have only a few plants as yet in this country, in operation, on this latest,

best method. Small plants, too. Europe has had some for ten years, so that we know what it is going to do,—know what it does, and we can, therefore, when we compare the different sewages, and differing conditions, take them into consideration, we
46 can tell pretty nearly what they are going to do in this country; and all that information was utilized to test this question here for the Passaic Valley Sewerage Commission.

Therefore, the Bay disposal was again recommended, and is now, and I would like to say here why, and why it is better than the others.

You know, of course, that it means disposal by dilution, and the question is, what does that mean?

Some twenty years ago I was engaged by the City of Chicago to determine what that City should do with her sewage. Twenty-one years ago. They wanted to purify it, and yet that subject was one that was very doubtful in its effects and so on. Very large expense. They had an opportunity, which very few cities, if any other, has, of diluting their sewage and discharging it away from Lake Michigan, that is, into the Mississippi valley, and, therefore, preserve the water supply, which must be taken from Lake Michigan, there being no other available supply. Now, then, this canal which was to take the sewage, diluted, into the Mississippi Valley, went through rock for more than half of its distance; it was very expensive, and it was necessary to find out how large must you make that, because every inch in width would mean a great deal of money in added expense of installation; so that all the available information, from Europe and America was brought together to find out what effect *is there* by diluting the sewage, and, to be short, the result was that
47 a certain quantity of water, passing by and taking the sewage of a given population, will so dilute the same, and mix it and carry it off, so that the oxygen in the water will purify that sewage and render it, after a due time, not at once, but after a due time, render it innocuous.

Now, the figure, if I may state it, was three and one-third, about three and one-third cubic feet a second of flow was necessary to dilute the sewage for one thousand people. That was the result and on that basis the canal was built, and it is there to-day; and, now, what do we see in that canal? We see no pollution. We see that even though the dilution to-day is but two and two-thirds cubic feet per second per thousand persons, therefore less than the amount we specified, there is no offense, and that without question that big water way is going down from Chicago to the Mississippi River, and there is no offense. That is merely the result of data that was obtained from Europe, from Massachussets, and other places in this country at that time, which enabled the Commission to make the recommendation, and it has turned out as it was *accepted*.

Now, we have a great deal more enlightenment now on that subject, both from Europe and here, and I will say that the imperial government in Germany possessed a lot of cities on the rivers in Germany, who purified sewage, before discharging it into the rivers, but it was a very expensive operation, and the consequence was that

all of the cities got to work and found out how to purify
48 sewage, and the result was that they found it was practically impossible or, better, unnecessary. Reports were made to the imperial board of health and the imperial board of health changed its dictum and now desires that a certain amount of water must go down those rivers to dilute the sewage of a certain population. It has thrown away the Chicago standard, and for good reasons. But the sewage must all be screened and settled, but nothing more. Now, all the cities are doing that: Along the Elbe, along the Ader, along the Rhine, and other cities; that is, they are not all completed,—the works are not all done, but they are going on in that direction. This was not an unknown matter to some engineers, and, now, every engineer that has studied this matter and had some experience in it would say that that was the way the thing was going to go eventually, and that the imperial German board of health was executing something which was altogether too expensive and unnecessary at the present time.

For that reason, the specification for this Passaic Valley Sewerage District sewer was made so that the sewage shall be screened and then it shall be settled, because, the first Board, of the first Commission said: "If you want to put this sewage into New York Bay, do you want to put it in like Hoboken, like Jersey City, right along the shore, or, how? I said, personally, I do not think that that is proper, because it is all one grand metropolis, and I should suppose
that that would be very objectionable, in fact, I think every-
49 body would grant that it would be objectionable; therefore, I proposed the method that you have been told about, at the time. Better than Hoboken discharges its sewage; better than Jersey City discharges its sewage; better than New York City discharges her sewage.

Now, here are the chief differences, why I believe this is the best system of sewage disposal for the territory under consideration. In the first place, the sewage has all its floating matter taken away at the pumping station; in other words, the sewage is screened——

Col. Ruffner: Won't you please explain that to the Board?

Mr. Hering: I was just coming to it: The screening is done in a number of ways in Europe. We have got about a half-dozen different plants and screens, one particularly nice, I was looking at, this Summer, being from two millimeters to an inch, two millimeters is about one-sixteenth of an inch, and experiments have been made as to how much can be screened out and as to what cannot be screened out, and you will naturally see that by screening you can get out all the coarse, floating matter you do not wish in evidence, and we do not need any evidence about it, it seems to me that the chief objection we all find in the New York sewage, which is not screened out, we see it coming down, floating down both rivers; we see it, and we know it is sewage, and we don't like it; that is the reason for screening the sewage in Europe, almost everywhere, that is the reason we contract to screen it here, so that none of it will float down the water any more.

50 The next thing is that we take out the sediment, in order to prevent this sediment from depositing in the channel and

filling it up. This was done after a consultation with General Roberts and General Raymond, of the Army, and no details have been made as to just how much sedimentation should take place; but sufficient to satisfy whatever demand the United States Government may make. Now, that is proper, so that those two things are out. Then, thirdly, the sewage is not discharged at the shore, like that of Jersey City, or New York and Brooklyn, but nearly one mile from shore, and, for that reason, the effect of the New York sewage going down along the piers, which is taken up by the same thread of water, and where there is, an accumulation, instead of dispersion, does not take place,—it is out in the middle of the Bay, nearly a mile from the shore.

The next point is that the sawage is discharged forty feet below the surface. Now, that is a very important matter,—in fresh water, and, also, in salt water. You can readily see that when the sewage is discharged down, far below the surface that, as fresh water, it will rise in salt water, it will rise up towards the surface if left alone, and the surface gets quiescent, and it may be apparent there. This is so in Boston; it is so in many other cities where they discharge large bodies of sewage in salt water some distance below the surface. Now, I do not know of any place where it is discharged as much below the surface as it is intended to be here, nor in the way it is intended to be, and as it ought to be, but my experience, I will
51 say a litt'e experience I had in Honolulu helped me somewhat in this conclusion. The experience generally in Europe has, as elsewhere, shown that this sewage will be dispersed as it rises, the only question is, into how much water shall it go,—how much sewage into how much water, and, as a provisional only, I assume, for the case here, the same dilution that I recommended to Chicago, which is provisional, knowing very well that this is salt water and Lake Michigan is fresh water, but it gives a foundation, and I am not certain as to just what is the actual best dilution because there seems to be no careful investigation on that subject as yet, and it is not very simple or easy to make. For that reason, I suggested a number of small outlets,—think the number was four hundred small outlets, to be placed upon this sewer, across the current, so that the water, moving into the Hudson, and into the rivers and Bay and out, would pass those openings and take from each one an amount of water just about equal to that which renders the Chicago Sewage entirely inoffensive. Therefore, it was necessary to issue the sewage in small amounts in small pipes, across the current and, as the report which you have shows this method has been adopted by the present commission; it is a dispersion of the sewage better, I think, we may say, than in any other city in the world except possibly Hamburg; but that is a very small affair, and is not nearly so effective as this, although that is the best that could be done there.

In Hamburg, the sewage is screened and settled the same as here
and is discharged into the Elbe across the current just as
52 is proposed here, with a number of small openings just as is proposed here, although there, perhaps, not so thoroughly

worked out as may be done in this case under different and somewhat better conditions. There, what is the result? All of the Hamburg sewage goes out there; you don't see it at the surface; ships go back and forward over the place where, thirty feet down, the sewage is discharged, at a depth of thirty feet; all the vessels pass there and see no objectionable results in the water and the people are perfectly satisfied. The tide there is about six feet, it runs up and it runs down, but I don't know how many, perhaps ten, miles below this City, not more than ten miles below, in the current of the stream, the City of Albany, a large City, with a large population, takes its water supply out of the Elbe, into which the sewage of the City of Hamburg has passed under the conditions described, it takes its water supply, filters it, and, at the time when the cholera was in Hamburg, when the cholera sewage went right into the river, therefore was taken up by the intake of the Albano water works, yet there were no cases of cholera in Albano excepting those who drank water in Hamburg,—one of the most remarkable cases on record in the world; they drank that water, and they drink that water today, and they do not object to it, and they do not think of getting any other source.

Now, I believe, Mr. Chairman, that that is all I wanted to say about the method of sewage disposal, which I thoroughly believe is the best that can be made, and I only wish to say one
53 more thing: I hold the position of consulting engineer to the Board of Estimate and Apportionment of New York City and I would not for a moment allow myself to say a word which would in any way affect the best interests of New York City, and I believe that there is no way to dispose of the sewage of our neighbors that is better than the one that has been recommended.

Col. Knight: Will you kindly go a little more into detail as to the passage of this sewage backwards and forwards with the tide? How far down stream would it go from your effluent there?

Mr. Hering: It would, naturally, go as far as the water of the river would go during the incoming tide, and then it would go back and down as far as it would travel.

Col. Knight: Have you determined any limits in any of the reports you have submitted?

Mr. Hering: No limits of distance, because it don't seem to us to be very essential, for this reason: that the sewage is diluted, so that it is not feasible—I want to state one thing, please, which is a proof demonstrative—to demonstrate just what I say, some might say, oh, that is all very good reasoning, and perhaps a good deal of theory about it, and in these questions it is well to have a practical demonstration, so I urged that a practical test be made. The Commission consented, and we procured a barge containing about thirty thousand gallons of fresh water, and representing sewage, and so that we could see the same, we put into it enough red aniline
54 dye to make it blood red, so that you could see the coloring plainly, well it was just like blood. Now, we went down to the point where it is proposed to discharge this sewage, this side of Robins Reef, and at a time when the tide met,—that is, I wanted

to get there at such a time when the water was as quiet as possible, because then it is very clear, and it seemed to me that when the water ran from four to five feet per second you would not see it very far any way, so I wanted the water as quiet as possible. We therefore discharged this thirty thousand gallons of adulterated water at the time when the tide went least—the velocity was least, and we found as follows: We found that when it was discharged ten feet below the surface, you could very soon see this blood-red water at the surface; naturally, that could be expected; the fresh water came up; it was lighter than the salt water. Then we discharged it twenty feet below the surface and we had to wait some time, and then it came up, some of it, but very much dispersed and not so vivid. All the rest of the water we discharged at thirty feet depth and although we were around there over two hours we never saw anything at the surface at all, not a thing of this red liquid.

That was a very crude experiment; it was really intended only to see how it would act, in order to get some practical details, and so the Commission consented to making that test with the expectation of some day having a test made that might prove it more thoroughly so as to be able to say that with this Passaic
55 Valley sewage, discharged out of a six inch pipe at a proper depth, at presumably as nearly as possible the real conditions, and the quantity, the width of water which was to dilute it would be about the same as in this project, although the details have not been studied out, as there has been no opportunity for doing it. I merely want to say that this proved that this assumption is correct in practice as well as in theory, although I do want to say that was theory in a sense, not being actual sewage, but it is not speculation, because it is not—there is enough evidence given here as to the practice at Hamburg, Germany, as well as in our own country to remove that from any charge of speculation whatever.

Col. Knight: Another question, Mr. Hering: As to the proportion of solid matter in sewage, the proportion you will remove by screening; the proportion that will still remain subject to sedimentation?

Mr. Hering: The proportion which can be screened out varies, of course, with the size of the openings between the pores of the screen. Now, very elaborate experiments were made in the sewers of Berlin on the subject of screening and with different size mesh, and it was found, with the ordinary screen, going down to about a centimetre in opening—a centimetre is about a half inch, about a half inch opening in mesh you can get out more than fifteen per cent. of the suspended matter, but you get out everything that is larger than a half inch. The other suspended matter is very small and remains in the water; it is what renders the waters dark, but it is
56 so small,—the partices are so small that they cannot be seen as particles, their presence merely serving to darken the water.

More recently, experiments have been made with screens down to a still smaller size, down to a millimetre in the size of the pores, and, there, a much larger percentage was taken out, I believe about one-quarter, but the three-quarters remaining in the water corresponds in size and effect to what is in the water after a rain, causing the water

to look brownish; it is so small as to be almost impossible to screen out with any contrivance of this sort we have been describing; it has to be filtered out; but that would go through the screen, even down to a millimeter size of mesh; but there is nothing, that amounts to anything, in the sewage in a sewage system such as this we contemplate, that is not to take in, after it is completed, any storm water or any surface water, which is objectionable, all the larger particles, all that floats, has been taken out——

Col. Knight: You still have not touched the point, Mr. Hering, you commenced in one particular, but you have not developed it; my idea was to get your idea of the proportion of solids to the amount of sewage,—then the amounts removed by the different stages?

Mr. Hering: This is the figure we usually use; of course, our sewage is very much more dilute than that of Europe, and we must take that into account. We assume that there is one part of solids in five thousand parts of water, about. But the solids are very small; of course, everything that is solid is included in that.

57 But sewage, you know, consists of, we will say, organic matter and mineral matter in about even parts and, together, they only amount to about one, that is, to about three or four parts of water to one part of such matter in the sewage; that is the ordinary house sewage, in that composition.

Col. Knight: Of that, you will remove, by screens, then, fifteen to twenty-five per cent?

Mr. Hering: Yes; and that means, that we would remove one hundred per cent. of the matter that you would see floating.

Col. Knight: Then, what remains after the sedimentation? That would also take out a small part of the grit that screening had not?

Mr. Hering: That would take out the greater part of the grit that screening had not; that takes out the grit; whatever will deposit. Now, that is a subject that has not been studied yet very much——

Col. Knight: I noticed you leave it vague.

Mr. Hering: It is left vague because it takes a great deal of study and expense to find out those details; they simply have not been attacked yet; it was the understanding, of course, of the Commission, that whatever was necessary to be done would be done. Rough estimates have been made; I cannot tell you just what those rough estimates are, any more, but sufficient, I am quite sure, to cover whatever sediment would come in.

Col. Knight: And when the application is made for a per-

58 mit, it includes sedimentation, simply to include things that may arise and have not been accurately determined yet?

Mr. Hering: This quantity is not accurately determined yet, but the fact that sedimentation shall be there and the basins shall be large enough to allow the velocity to be small enough so that matter of a certain size will deposit,—that has all been determined. You are aware, perhaps, that the matter carried in suspension by water, given a certain velocity of the water, if you reduce the velocity, you cause the suspended matter to be deposited; it is an entirely fixed ratio.

Col. Knight: Well, the screening station here, the location of the

pumping station, is right on the edge of the water? (Referring to map.)

Mr. Hering: Yes.

Col. Knight: Now, where do you get any sedimentation basins—(referring to map) where are they to be arranged for between that point and the point of discharge?

Mr. Hering: It would be arranged above the pumping station—the screening and gravity basin would be above the pumping station——

Col. Knight: So, your screens and gravity basins are away down there (indicating on map)? They are supposed to be there (indicating) before you come to the pumping station?

Mr. Hering: Yes, sir.

59 Col. Knight: Now, just whereabout, in this route, whereabouts is that development—the commercial development that the City of Newark proposes—the Canal?

Mr. Hering: I cannot tell you that.

Col. Ruffner: I would like to ask you if you propose to do that small screening at all before you reach the pumping station, or only there?

Mr. Hering: Whatever screening is necessary and whatever disposition is necessary to facilitate the pumping that is to say, not to injure the pumps, will, of course, be done at local stations, and all that, of course, will again be screened at the pumping station.

Col. Ruffner: That is, you expect to do screening and sedimentation in each of those local stations, before you reach the pumping station, and there also?

Mr. Hering: Yes; the screening and sedimentation at the pumping station will, of course, be on account of the pumps.

Col. Knight: It has been determined at Hamburg—that question of sedimentation—that question has been practically put in use at Hamburg?

Mr. Hering: Yes, sir.

Col. Knight: Have you any idea as to the results?

Mr. Hering: Well, the results are very good, of course, they must dredge the rivers there; but, there is no complaint whatever that I could hear of that the sewage is silting up the channels there.

60 Col. Knight: But what do they remove? Do you know anything about the proportion removed by sedimentation?

Mr. Hering: I cannot remember. They have a very small settling basin there by screening all the large matter.

Col. Knight: That is all?

Mr. Hering: That is all I know. That is right at the screen. Right at the screen; the settling basin is only about as large as this room (about 80 by 20*) but the system is only for the City of Hamburg,—the plant is not very large. That is all. And they get out everything they think is necessary, and they are entirely satisfied with the results, and the shipping traffic which passes right over the discharge points makes no complaint, and seems to have cause for none.

Mr. Dean: Did I understand, Colonel Lockwood, that questions might be asked after the completed statements?

The Chairman: After each individual, yes.

Mr. Dean: I would like to ask some questions of Mr. Harrison, as to his statements, and of Mr. Hering, subsequently. I would like to go into the details of this project——

Mr. Lebkuecher: Mr. Chairman, might we not be first heard here? There are here a number of representatives from the Passaic Valley district, and we want to make a full expression of our case; many of them cannot remain here very long, and this questioning can come later, if you please.

61 The Chairman: I think that might be as well—what do you say, Mr. Dean?

Mr. Dean: It is entirely agreeable to me, provided the gentlemen whom I desire to question in order to obtain the details of this project can be detained to answer those questions subsequently?

The Chairman: Well, Mr. Lebkuecher, you can arrange that?

Mr. Lebkuecher: I understand Mr. Dean wishes to question Messrs. Harrison and Hering, and they will be here after the presentation of our case.

The Chairman: Well, then, you may proceed.

Mr. Dunn: I have been obliged to give this subject considerable attention, both as a property owner in the Passaic Valley, as a taxpayer in the Passaic Valley, and, as a lawyer, protecting our city of Paterson, as its counsel, from attacks which riparian owners below our city have found it necessary to make against the city in order to cause it to desist from further discharging the sewage into and polluting the waters of the Passaic River, and, in consequence of that, I have also had occasion to give considerable study to this subject in connection with the Passaic Valley Sewerage Commission, which was first organized in 1896 and, from that time down to the present time, I have been in close touch with all their investigations, and know the work that they have been engaged in.

Now, the principal point, is seems to me, in addition to what has been stated to your board by the engineers here, to which

62 attention should be called, is this: Why is it necessary that there should be an improvement of this kind in this Valley? and, who is it going to benefit?

Now, in the first place, I want to call your attention to the fact that in this Valley is represented one-third of the taxable ratables of the State of New Jersey. I want to call your attention to the fact, another important fact, that in this territory is represented one-third of the population of the whole State of New Jersey; and I want to call your attention to another fact,—that there is no piece of territory in the State of New Jersey to-day of such future, with such a promise, with such an outlook for development, that the Newark Bay, the property around Newark Bay and the Passaic Valley has if we can only get this relief for which we are now seeking consent from your Board. Now, the reason for that follows: The Passaic River is an open sewer, and it has been an open sewer, and, in consequence we must find some relief.

The City of Paterson, located as it is, at the upper end of this improvement, at the foot of the Great Falls, and the greater part of this City, its residential section and its factories, located along the River, as it winds through the City, is in such a situation to-day that we almost have to come to you appealing for help, for this reason: The character of our soil and the topography of our ground is such that there is no land South of our territory available, and we cannot go North because that is all up hill; there is no land lying
63 South of our City as it lies, there is no land South at all available or suitable for sewage disposal work; there is no land that we own East of the Passaic River, and that is in Bergen County and in foreign territory.

We have been annoyed for a considerable time by these riparian owners whose property was being disturbed, whose land was made unsalable principally because of the pollution we were discharging from our factories and sewers into this River, and in 1901 they started suit for an injunction against the City; we resisted and defended ourselves against the suit,—the litigation was prolonged in consequence of this question, whether Paterson should be responsible to riparian owners for the damage done to their property or for only such proportion as was done by the discharge of the factory waste and pollution through her sewers, the fact being that along the river there are thirty-seven factories, dye houses, silk mills, locomotive shops and so forth, giving employment to ten thousand men and which discharge their sewage directly into the river; so that was the main question, the main question of discovery before the Courts in that litigation was as to the proportion of damage, and which has just resulted in a decree by Vice-Chancellor Stevens compelling us to pay a sum amounting in round numbers in damages and costs, to Thirty thousand dollars; in addition to that we have spent in the neighborhood of Twenty thousand dollars in protecting and defending ourselves; and that injunction is against us, to take effect by March 26th, 1911, that unless Paterson by that time
64 makes an honest effort in finding a way to dispose of the sewage by March 26th, 1911, that injunction will issue, and unless the court of equity for good reason believe that such an honest effort has been made as in equitable terms may be so deemed, then and in that event the City of Paterson will be liable to the riparian owners in damages and compensation may be given and relief granted, so that we are now under mandate of the Court of Chancery to get that sewage out of these waters and cease polluting these waters by March 26th, 1911.

Now what else is our position The act of legislature which established the Passaic Valley Sewerage Commission, creating it, and which has come before your Board with an application for the best, and only system for purifying this water, under which this application is now made to your Board, that act provided that on December 12th, 1912, all persons polluting the Passaic River from Newark Bay up to the Great Falls should cease, and above the Great Falls the Passaic River or its tributaries, so that we have been informed by the Passaic Valley Sewerage Commission under that act that we

act within these provisions, so that even if the Court of Chancery should grant us an indulgence after March 26th, 1911, we would still be under the ban of that act, we would still be under the ban of both the courts and the sewerage commission, forcing us to get out of the river.

In addition to that, following along the banks of this river
65 is some of the most valuable and desirable property anywheres in the land is located, convenient for transportation, for factories, if we could do what the City of Passaic has been able to do for years, and we have not. Paterson has not been able to get new industries into the City because we have never had a place where their people and the factories could discharge their sewage their effluence without being liable to suits from lower riparian owners, so that the Passaic people have been able to get in more right along, and another important plant has just been located there, to cost a million and a half and to employ three thousand hands. But since Paterson has consented to unite with this Passaic Valley Sewerage Commission, what has happened to us? Right here, across River Street bridge, right at this point (indicating on map) there has been projected and is now being built a factory to give employment to five hundred men, the factory costing Four hundred thousand dollars, but this undertaking was located in our City with the precise understanding that we are to be able to get the consent of the Commission—the Passaic Valley Sewerage Commission that they be permitted to discharge their sewage—their effluence into the sewers.

I am speaking of this merely as an example illustrating the great future there will be for this district once we get a place where objectionable effluence can be discharged into this sewer without doing harm to the lower riparian owners. Now, why we should not have this future I cannot understand. There is Newark being permitted to develop all this territory in here (indicating on map).
66 Why, just take New York as it is now and as it has been in our time, and see how it has developed: You will remember the time here, fifteen years ago, you could readily buy practically all the land you wanted, the upland here (indicating on map) for a song, now the price of land of every kind has gone up so that you cannot buy it to-day, you can get a lease, or take more than you want to put into it, and coming down along Newark Bay here (indicating) you can hardly get dockage.

What is proposed here is to improve the great territory lying around Newark, available and suitable for such purposes. Here is Newark, with all her thousands of acres of land here (indicating) kept undeveloped. Why, I have been informed that at the Clark Thread Works, the stench from the river is such in warm weather that they have had to allow their employes to go home, although they have kept the windows closed on warm days. And at Passaic, in the filtration works, Mr. Gardiner, of the Water Company, has told me that the stench is such in the afternoons that they had to close down the works.

Now, then, we ask you if, in view of these facts, in view of the

fact that here is the city of Paterson obliged to pay Thirty thousand dollars in damages to those riparian owners because their property has been made unsalable, because sickness and ill-health has been produced in families and children, as testimony adduced there proved, because other people down along this shore are complaining of this nuisance, can it be said that this great benefit should be withheld from this great valley?

67 Now, then, another point that I think probably it would not be improper for me to make adversion to.

I understand that there are some people in the State of New York who entertain the opinion that they ought to object to this improvement—who have entertained the notion that this improvement ought to be objected to; just why, I do not know. We are neighbors and we should be neighborly, but there is an impression among certain men that they always ought to be appearing as objectors to any improvement going on.

Now, it seems to me that they ought not to take New York City, Brooklyn,—Greater New York as a pattern and come before this Board, representing the Federal Government, and make an objection to an improvement which means so much to the public health of all of our State, and which means so much to the industrial development of the territory there when they stand right here discharging raw sewage and street sewage right into the waters of the Bay.

But they say, "Oh, well, you ceded to the State of New York, the right to exercise dominion over the waters of this Bay and the waters of New York Harbor, and, therefore, New York people, and those who are responsible, are entering complaint, and you must come and consult them before you can build an improvement of that kind in the Bay". Now, in a word, to answer these objections, let me simply say this: I have given considerable study, careful study and investigation to those suggestions, and, in the first place, I say that

68 the position which the State of New York takes upon the question of nuisance is settled by the case of the State of Missouri against the State of Illinois in the case of the Chicago Drainage Canal. The Supreme Court of the United States has just rendered a decision and has said to the State of Missouri, "so long as you and your cities continue to pollute the waters of the Mississippi River, you do not stand in court with clean hands and until such time as you can prove that the evil of which you are complaining is produced alone by the Chicago Drainage Canal, you have no standing in equity."

Now, where does the State of New York stand, in equity, with clean, or dirty, hands, in making an application against New Jersey, for an injunction against the State of New Jersey, because it may happen to pollute the waters of the Bay, according to our engineers not in a lifetime, not in the lifetime of any of us and not in centuries with the present growth of population, will the Bay be incapable of taking care of the sewage from the population, as stated by Mr. Hering, and which all engineers have conceded is correct. So that, they will say to the State of New York that it is premature in trying

to have the Supreme Court of the United States imagine there is a nuisance there, of which they cannot adduce any proof.

The City of Newark applied for an injunction against the City of Passaic, in 1882; they wanted to build a sewer system in 1882, and the City of Newark was getting its water supply there and she very properly thought that when the City of Passaic, with sewerage from a population of thirty thousand, would render the water unfit by
69 pollution. Now, what did she do? She went into the Court of Chancery and asked the court of chancery to grant an injunction, but the Court said, "no; that is not a principle of equity to enter an injunction in the case until such time as you prove the nuisance, until the injury is shown, we will hold off our hands and if, after such a time if it is found they are committing a nuisance there and do not abate it or modify it so that it ceases to be a nuisance, then the Court may act." So that the same principle invoked by the New Jersey court is applicable to the case here.

Just a word more: In saying that this great amount of money should be applied—the City of Paterson, in order not to be tied fast to any proposals of this very Commission and their very able engineers,—there was a feeling among our people that the cost of our apportionment of over Two million dollars was very heavy, considering that our total ratables at that time were fifty-eight thousand, although more now, being some ninety-two thousand,—that apportionment was made also seven years ago, and it was simply submitted to our people as a basis to work on, and the feeling was that every effort should be made to secure the very best results for the amount involved, and so we had Mr. Allen Hazen make a study and investigation of this whole subject and recommend to that City what was in his judgment, what was the most feasible, economical and practical and effective plan to adopt, and he recommended—he had studied the whole subject, both in this country and abroad,
70 and he said that the plan which seemed to him as the one best plan was to erect a rock dam, across the river, in Dundee County and there install a sewage disposal plant, and he recommended that we immediately buy there five hundred acres of land and clear it up, right over the river here (indicating on map) South of this line, right in that (indicating) territory there which might be used for a disposal works. But there was no law in the State of New Jersey that permitted the City of Paterson or any other municipality to do this or allowed them to go out of their own territory and erect a disposal works. So, we went to the Legislature in the following Winter, and we presented to them the matter in full, including all of the recommendations, and the Legislature passed a law thus far: "We will grant to Paterson, or any municipality in New Jersey, permission to build a separate sewage disposal plant provided there be no objection on the part of the authorities in the territory in which the work is to be performed or from other persons having a right there at present."

We subsequently consulted with the authorities in Dundee County, and they said: "No, you cannot put up any out-house on our ground; we won't let you destroy a lot of land here",—and Mr. Hazen

says the smell, in his experience, would affect the value of land within a considerable radius of the disposal works, and so, as I say, we cannot build a separate disposal work on our own lands, and we are cannot get land on which to build it, and so we said, let us go to the Passaic Valley Sewerage Commission and say "We want
71 to join you, join with you and our other sister municipalities here in trying to develop the resources of this territory and protecting the public health," and I submit to you, gentlemen that in view of the great benefit that is coming from it, in protecting the public health, developing property, improving the condition of such a large proportion of the population of the State and thereby increasing taxes and building up the commerce of the country, and in view of the evidence that navigation is not likely to be interfered with by the improvement, that you will not withhold your approval.

Mr. Lebkuecher: I understand fully that it is not necessary to explain to these gentlemen or this Board that a nuisance exists in the Passaic Valley——

The Chairman: It is within the personal knowledge of most of the members of the Board——

Mr. Lebkuecher: But I would like to have Mr. Eastwood, being the representative of one of the Boards of Trade along the River, tell you his views.

Mr. Eastwood: Mr. Chairman and Members of the Board, I am neither an engineer nor a lawyer, but a plain business man, a resident of the Township of Belleville on the banks of the Passaic River,—born and raised up there. I can remember when the Passaic River was one of the most beautiful streams in this country, perfect in every respect, its waters of the utmost purity, drunk by the citizens of Jersey City and Newark. Some years ago both of those large corporations were compelled to discontinue the use of
72 that water and secure a supply at other points at large expense. Since then, by the increased amount of sewerage deposited in the Passaic River, matters have come to a very terrific condition at the present time.

As a resident along that river, I am here to-day in the interest of this application before your Board. We have got to have relief in the Passaic Valley. We are now losing a certain amount of our population along the banks of this river. Our manufacturing interests are at a standstill, that is, as far as any increase in capital or enlargement of factories is concerned, for the simple reason that you cannot get any large project to locate on the river to-day owing to the condition of the atmosphere during the Summer. As one gentleman has very appropriately stated here, many of the factories have been compelled to close down their operations during the Summer when these extremely disagreeable conditions exist. No man who is in business can fail to appreciate what that means, and also that capital, when it is aware of such conditions, will not invest in or create any enterprises in such a locality.

Now, this matter of the Passaic Valley trunk sewer has been fought out for many years. I believe I am one of the first who adopted or advocated, rather, the trunk sewer. A number of years

have been lost to the people of Passaic Valley by securing proper legislation and by ascertaining the question so as to educate the people up to a point where such a thing is possible.

I must say that I, with great pleasure listened to the gen-
73 tleman who spoke last; it was an eloquent moment to have Paterson come before this Board and advocate the adoption of this trunk sewer and the granting of the application to your Board to deposit this sewage in New York Bay; it is a great pleasure to every gentleman who has been interested in this project since its inception.

Now, in our little town, right above the City of Newark, North of that City, we are in a terrible condition. Not only has property depreciated in value, but it has had a tendency to drive people away from the River, for we cannot keep our property in proper condition. Anyone visiting that town will notice the condition of the houses there; there is not a house there to-day in respectable condition as far as paint is concerned; it makes no difference if you paint the houses three or four times a year, the gases arising from that river take the color out of the paint right away, so that every house there looks as though it had not had a touch of paint for twenty years. I merely state that to show the condition of the atmosphere. That is why we are here to-day, on behalf of the Board of Trade, of the first district of the Passaic Valley Sewerage Commission, asking for this application and for relief, and we think that under the circumstances, that while the City of New York and the City of Brooklyn are placing their sewerage in this Bay, that the State of New Jersey ought to have, if it does not, the same right in this Bay,—it should have an equal privilege,—if they are putting this inculms into the Bay in its raw state, we should have the right here applied for, as if it be not granted it will work the prac-
74 tical destruction of our community.

Mr. Sherrard: Mr. Chairman, and Members of the Board, I only want to speak of this question from the standpoint of the City of Newark; that city, as your Board knows, is already committed to the large scheme of a deep water harbor and dock improvements on Newark Bay, and we know that with the crowded conditions of the New York Harbor will bring this portion of the City of Newark very much to the front, and also all of Newark Bay, and it seems to us as we have looked at this project—I think the Chairman asked us to its location—the location is about four thousand feet to the South of where the tunnel and sewer pumping station is located on this map (indicating).

Now, the proposition of coarse screening and the provision for sedimentation, on this large project, would, in my judgment, relieve the Passaic River and Newark Bay of a good deal of the present deposit which has been a detriment to navigation, and on that one point alone, as has been shown by Mr. Harrison, this continual holding back of the flow of the river causing a deposit in the Bay, is a detriment to navigation, and the pumping out of this portion of the sludge in the sewer will to that extent be an improvement in the

condition of navigation in that vicinity—of Newark and of New York Harbor.

Mr. Lebkuecher: The Mayor of Paterson is here and will hand in a paper, which he would like to form a part of the record of this hearing.

Mr. McBride: Mr. Chairman, and Gentlemen: I do not
75 propose to take up your time, but I would like to present this paper, for your record:

(Mr. McBride here presented the following paper):

"The City of Paterson, in the year 1868, began the construction of sewers discharging into the Passaic River. This action was taken under the authority of an act of the Legislature of the State of New Jersey entitled "An Act to Authorize the Construction of Sewers and Drains in the City of Paterson," approved February 26, 1868.

At that time, the only method of sewage disposal in use in this country was that adopted by this City, namely, the discharge of sewage into running water. Such action was taken in good faith, with the belief that this City had a legal right so to do, and that it was the best and only method whereby the public health and public interests could be subserved.

With the advance of time, of sanitary knowledge, and increase of population, it was found by the City of Paterson in consequence thereof, that such discharge of sewage into a river of the size of the Passaic, was inevitably the cause of a public nuisance. From this nuisance the City of Paterson, through its discharge of such sewage, has itself suffered more than any of its neighbors.

As long ago as the year 1894 the attention of this City was called to the then existing conditions of nuisance, by the local Board
76 of Health. This City was then called upon to defend itself against the charge, that it was the chief cause of the pollution of the Passaic River. This the City denied, and denies now.

In our opinion, the chief sufferer from our own pollution is the City of Paterson itself, and not our neighbors below. We firmly believe that the Passaic River has sufficient volume and diluting capacity to care for the sewage of Paterson alone, without causing any public or sanitary nuisance to those situated below us.

Unfortunately, however, other communities possessing the same rights and privileges granted by the Legislature of the State, as we possessed, have utilized those rights and privileges, as we have, to empty their sewage into the river, until the bulk of sewage has become so great that the ordinary and natural flow of the river is insufficient to properly dilute and take care of such sewage. The result is, therefore, that to-day, and for the last 18 years, a public nuisance, by reason of such discharge of sewage, has existed in the valley of the Passaic River below the Great Falls.

Such nuisance, although in our opinion not affecting the public health, has unquestionably depreciated the value of property contiguous to the river, and has been a decided annoyance to persons living or employed in proximity to its banks.

The initial step taken by those realizing these conditions
77 and suffering from them, was the attempt to pass a general act, in the year 1892, forbidding the discharge of sewage

into any river, stream, lake or pond. This, the City of Paterson, through its official representatives, strongly opposed, and as a means of preventing the passage of such an act, which would be most inimical to the interests of the City, proposed in lieu thereof, that inasmuch as practically all the communities bordering upon the Passaic River were equally guilty, that they should combine and unite their interests, and jointly act in such a way as to remove such nuisance and purify said river. Official representatives of this City, therefore, were responsible for the preparation, the passage and the signing of the bill, passed by the Legislature February 26, 1896, and signed by our respected fellow-townsman, Governor Griggs.

Pursuant to this Act, Governor Griggs appointed, on April 21, 1896, as a commission, our late respected fellow-townsman, Dr. Elias J. Marsh, and Dr. H. C. H. Herold and William T. Hunt, Esq., of Newark; a better selection than which, from any standpoint, could not possibly have been made.

This Commission reported, on February 26, 1897, said report, in brief, being that the interests of the various municipalities bordering on the Passaic River below the Great Falls, were identical, and that it was to the interest of each and every one of these municipalities to unite with the others in a manner, namely, a joint
78 trunk sewer, to dispose of their sewage and prevent the existing nuisance by the discharge of said sewage into tidal waters.

This investigation has been continued up to April 1908. In the work have been engaged the most eminent engineers known to the profession in this country. The mere mention of their names is ample proof of the previous statement, namely:

Col. George E. Waring,
Alphonse Fteley,
Charles E. A. Jacobson,
Rudolph Hering,
James Owen,
Colin R. Wise,
Robert M. Watson,
William Ferguson,

E. W. Harrison,
Wm. Barclay Parsons,
Allen N. Spooner,
George W. Fuller,
George A. Johnson,
Samuel M. Gray,
Allen Hazen.

79 The work of two of these gentlemen was done entirely in the interests of the City of Paterson; one, Mr. Gray, being engaged and paid by an organization of the citizens of Paterson,

desiring the good of the City; the other, Mr. Hazen, being engaged and paid by the City officially.

All of these engineers mentioned, who have studied the problem and become acquainted with the conditions and requirements in the Passaic Valley, have agreed——

(1) That a public nuisance existed.

(2) That such nuisance should be abated.

(3) That it was to the interests, economically and from a practical point of view, to each and every municipality bordering upon the Passaic River below the Great Falls, to unite and work jointly to accomplish the abatement of this nuisance.

The question presented to the City of Paterson is purely a business one. The law of March 18, 1907, forbids this City to discharge its sewage, unpurified, into the Passaic River, after December 12, 1912. By an agreement, made through its official representatives, with the Court of Chancery, since confirmed by an opinion of said Court, the City of Paterson has been ordered to cease such pollution on March 26, 1911.

The City is therefore bound in honor, in law, and by the mandates of the Court of Chancery, to cease polluting, by its sewage, the Passaic River, on March 26, 1911.

The proposition, therefore, before the City, was whether
80 this result could best be accomplished by uniting with the other municipalities bordering on the Passaic River below the Great Falls, or by the building of a local sewage disposal system by the City itself.

As has already been stated, the eminent engineers who have given this matter their consideration and study, the universal opinion has been that the most economical and best way to accomplish the desired results was by union or by united efforts. All these engineers, except Mr. Gray and Mr. Hazen, have considered the interests of the District as a whole, and not the special interests of the City of Paterson. Mr. Gray and Mr. Hazen considered the interests of the City of Paterson alone, as distinct from those of the District, and reported on the advisability and the cost of local disposal systems.

Mr. Gray estimated the cost of a local disposal system for Paterson, at $2,670,185, such system being for the disposal of 25 million gallons of sewage daily.

The report of the Passaic Valley Sewerage Commissioners, under date of April 20, 1908, gives a capacity for the carrying away of the sewage of Paterson to the amount of 63,952,300 gallons per day, at an estimated cost to Paterson of $2,008,425.28.

Mr. Hazen (in whom this City has the greatest confidence, both as a man and as an engineer) was employed solely in the interests of this City, and gives an estimate of the cost of a sewage disposal plant at $3,028,190. In his report he advises as follows:
81 "In view of all the facts and circumstances as I have found them, and upon the supposition that a full, just and lawful arrangement with the other municipalities upon the Passaic River is reached, acceptable to the Legislature and to the Governor, I

believe that the interest of Paterson will be best served by joining with other municipalities in the construction of a trunk sewer to take the sewage from the entire district requiring sewage disposal facilities in the Lower Passaic Valley to a point of adequate sea-water dilution in New York or in Newark Bay near the Kill von Kull.

"I believe that this arrangement will be substantially better for Paterson than the separate local purification of her sewage."

Both the scientific and the economic side of this question have been most thoroughly studied, considered and approved by a Committee of the Taxpayers' Association of this City,—an Association without any motive except the preservation and advancement of the interests of the City, composed of citizens whose only incentive is civic pride and whose only object is the interests of the City in which they were born or lived.

Said Committee, after their investigation and study, reported as follows:

"We recommend that Paterson join with the City of Newark and other municipalities in an effort to secure the disposal of sewage by discharging it into the sea without treatment, other than screening."

The Special Committee appointed by me, the function of
82 which was to advise the officials of Paterson upon the subject of the most economical, the most scientific and the best method for the disposition of the sewage of Paterson, after a most thorough and exhaustive study of the work already done, and after personal investigation of the subject sufficient to satisfy themselves of the justice and right of their conclusions, reported in part as follows:

"That we have fully investigated the subject of sewage disposal and are unable to find any system of local disposal that would be applicable to the City of Paterson, and that, owing to the date set by the Court of Chancery, namely, March 26th, 1911, limiting the time of our use of the river as a sewer, it is necessary that we take some action without further delay.

"Therefore we are of the opinion, that in order to comply with the order of the Court of Chancery and of the General Sewerage Act of 1907, pertaining to the discharge of the sewage of the Passaic Valley Sewerage District, limiting our period for the discharge of sewage into the river, that this City should enter into a contract with the other municipalities of the Passaic Valley Sewerage District, and with the Passaic Valley Sewerage Commissioners, with the understanding that the City may withdraw if the cost of the proposed trunk sewer exceeds the present estimate of $12,200,000.00, paying our share for the securing of working plans, estimates and bids.

"We therefore recommend, that the Mayor and Board of
83 Finance be authorized to sign such contract as proposed by the Passaic Valley Sewerage Commission, and that this City pay its share for the preparation of working plans and estimates

and the securing of bids, leaving, however, the ultimate question of the joining in the trunk sewer plan to future developments."

The Board of Finance, acting upon the above recommendation, resolved unanimously to enter into a contract with the Passaic Valley Sewerage Commission and the other municipalities interested, for joint action in the disposition of their sewage.

The City of Paterson is therefore of the opinion that its best interests can only be subserved by union with the other municipalities of the Passaic Valley and the joint discharge of their sewage into tidal waters.

At the present time, the sewage of Paterson is discharged above the Dundee Dam and above the tidal waters of the Passaic River. This sewage is carried down and is now discharged through the Lower Passaic River, Newark Bay and the Kill von Kull, into New York Bay.

The joint action of the various municipalities contemplated does not increase this discharge of sewage but simply provides for the collection of such sewage as will, under existing conditions, inevitably be so discharged, and its discharge at another point in New York Bay.

The interests of our City demand, in our opinion, a joint system of sewage disposal for the Passaic Valley."

Mr. Lebkuecher: Now, gentlemen, I do not think it is necessary for us to call any more, perhaps, of the people who are here at your invitation——

84 Col. Knight: There is one thing,—these gentlemen who have been called might be requested to remain until opportunity has been given for such questions as the opposition may wish to ask.

Mr. Lebkuecher: I will arrange for that,—I have already asked them to remain.

Mr. Heck, of the Jersey City Board of Trade, would like to address the Board in behalf of the application.

Mr. Heck: I only wish to say that, on behalf of the Board of Trade of Jersey City, and not only do I appear as a member of that Board, but as one of its Board of Directors, a few, a dozen or more, of whom are here,—that that Board has carefully considered the plans of the Passaic Valley Sewerage Commission and are in hearty accord with all that the Commission has determined and are supporting it fully; that we know the present conditions, that has all been said and that is about all to be said; we could only reiterate what has already been said. We think it is an improvement, that would affect Jersey City materially, as well as Newark Bay. A good portion of our City is bounded by Newark Bay,—the upper portion, by the Newark Bay and the Hackensack; it would also be an improvement to Jersey City flats and Bayonne Neck, and we think this matter of sedimentation and sewage in the Passaic Valley and Newark Bay ought to be done and as speedily as possible.

I am the representative, also, of owners of land in the lower portion of Jersey City, in the neighborhood of this project and now in

the way, will have to be applied to personally for privileges,
85 and I can say, personally, as representing eighteen or twenty acres, that we will in no way interfere with the project but hail it, and we thoroughly advocate the adoption, or, at least, the consent of your Board to the privileges now sought for.

Mr. Payne: I am here, representing the Riparian Commission of the State of New Jersey, simply in answer to the invitation of this Board, and I have nothing to say in addition to what has been so ably said.

The Riparian Commission is intrusted with the improvement and sale of its riparian lands, and anything that would enhance or raise their value is, of course, in line with their duties, and they feel sure that the Commission in the direction of this important work, are attending to it properly, and I have nothing further to add.

Mr. Lebkuecher: I do not think it is necessary to call any more advocates after the presentation that has already been made; there is only one thing I would like to add, and that is,—when this project of discharging the Passaic Valley sewage into New York Bay was first brought forward by the engineers employed by the Passaic Valley Commissioners, we, as commissioners were uncertain as to whether that was the proper thing to do, and we were told by the engineers and assured that it would cause no pollution whatever.

The question also came up, advanced by other people in the State, and the Legislature passed an Act that we should first find out, and get the best information possible as to whether there would
96 be any injury in New York Bay, by reason of this discharge, if discharged as proposed, after screening and sedimentation.

In pursuance of that Resolution of the Legislature, the Commissioners got the opinion of a number of experts from the Army Board, and we have here ((handing the Chairman a paper) our report, giving the opinion of General Henry M. Robert, Lieut. Col. C. W. Raymond, and C. S. Greene Jr., Civil Engineer, and I would like to submit it as accompanying our application.

If there are any questions to be asked, these gentlemen are ready to be interrogated.

Mr. Dean: The State Commissioner of Health, Dr. Porter is here, and says he will have to catch a train back to Albany—

The Chairman: Dr. Soper was going to address the Board—

Dr. Soper: Mr. Chairman, if you will hear those who are down on the programme when their names are called, they can make their remarks—the questions might come afterwards—otherwise a number of people here I know want to go out of town and it is impossible for them to come back, and they will not have an opportunity to be heard.

Mr. Dean: It is absolutely necessary for me to ask certain questions, to cross-examine, some of these witnesses for the reason that they have not given certain details it is necessary to have in order to understand the nature of their application entirely—

87 Mr. Riker: I do not think there should be a cross-examination of our witnesses; there is a litigation pending between the State of New York and the State of New Jersey, before the Su-

preme Court of the United States, and I understand that the gentleman who is on his feet represents the State of New York, and I do not think that the witnesses on behalf of the State of New Jersey, if he so terms them, should be subjected to a cross-examination, and I think nothing should be asked of those witnesses except what is actually germane to the subject-matter before this Commission. I do not think there should be a fishing excursion for evidence against the State of New Jersey.

Mr. Dean: Mr. Chairman, I am not on a fishing expedition; I want to find out what is going to become of this sewage. I wish to find out what the specifications of this Commission consist of? As the representative of the State of New York I believe we have the right to find out whether this sewage is going to interfere with the navigation of this harbor. It is true that the United States Government has the primary right over the navigable waters of this State, but the law is well-settled that the State of New York, or any State in which are navigable waters, has a secondary right, and that is what we wish to invoke, and it is for that purpose that I want to bring definitely to a head just what this screening chamber, this gravity chamber is to consist of,—what is the size of the dispersion area, and the size of the solid matter in suspension, and how
88 it will affect navigation with reference to the largest of the big ships which enter this harbor, representing investments of millions of dollars, and, consequently, the commerce of this State and City.

The Chairman: You only want the engineers?

Mr. Dean: Yes, sir.

Dr. Soper: Every one of these men (referring to names on list) may go out before Mr. Dean, or one of your Board has put questions to the engineers with regard to this matter.

Mr. Miller: I have no especial status here, except as I represent the Department of Justice, and I did not wish to interrupt the presentation of the case by the proponents, in order to ask certain questions as to the bearing of the application with reference to that Department, and I am perfectly willing to wait and suit the convenience of this Board. I want to know, on behalf of the Department of Justice what effect this will have upon commerce and navigation, and, of course, that can be brought out by other methods. I do not want to ask any questions, and I therefore hope that the gentleman representing the State of New York will bring out such information as desired, of course, subject to the right of New Jersey to answer or not.

The Chairman: Mr. Miller, this Board has been deputed to hold this hearing, and they are men who have had experience in this sort of work for a good many years. I think the mind of the Board is pretty well made up as to what information they want. We want the information covered by the endorsement of the Chief of
89 Engineers in sending this matter to us. I do not like the idea of bringing in technical matters, if it can be avoided——

What is the sense of the Board? Shall we give Mr. Dean an opportunity to proceed to cross question the witnesses——

Col. Knight: I do not like the word cross question or cross-examine; I should prefer the word "question."

(The sense of the Board—after a moment's discussion.)

The Chairman: You may proceed, Mr. Dean, to question the speakers who have made their presentation.

Mr. Dean: I would really prefer to let the other speakers get through, and then ask such questions as I may——

The Chairman: Then that may be done.

Dr. Soper: Mr. Harrison has made the chief remarks of a technical nature, and described what was intended by the Passaic Valley Sewerage Commissioners.

I will not attempt to reply to many of the statements which he made, although I am very strongly tempted to do so. I am sure that some of the fallacies which have been fallen into and stated by Mr. Harrison, will appeal to others who will speak here before your Board——

Col. Knight: But, Dr. Soper, please do not give us anything by indirection: If you have anything to criticize or to comment upon in a person's statement, if he has made, in your opinion, an error, please refer to that error directly.

90 Dr. Soper: I would call attention, as one error, to the fact that the disposition of sewage in the New York Bay, and its effect, has been largely based upon the observed effects of the disposal of sewage into fresh water, and to state that the effects, particularly with regard to sedimentation of solid matters in salt water and in fresh water, are quite different.

I have an exhibit here to offer in that connection. Sewage sludge has been mixed with fresh water in one bottle and an equal quantity of sewage sludge with salt water in another; the bottles have been allowed to stand, in this case, one hour; the clearer bottle shows the effect in salt water, where the sewage sludge is deposited much more rapidly than in fresh (Referring to photograph of exhibits mentioned). In this case (referring to separate photograph) the exhibit shows the effect of three hours' standing.

Col. Knight: Have you any volumetric determination as to the amount of dispersion?

Dr. Soper: None has been reached.

Col. Knight: This is merely a question of experience?

Dr. Soper: A question of experience.

Attention is called also to the fact that the specific arrangement for screening and settling and discharging the sewage are not given in the report, and have not been given by any of the gentlemen who have spoken here this morning.

You are requested to form an opinion on the statement that the necessary works will be constructed. The Metropolitan
91 Sewerage Commission has requested of the Passaic Valley Commissioners information on this point and has been no more able to get it than your Board has this morning.

The rest of my remarks, for the sake of accuracy, and to economize time, will be read; and are:

"The Metropolitan Sewerage Commission is an official body

created by the State of New York to investigate and report on means for permanently protecting and improving the sanitary condition of the waters of New York harbor and vicinity. Its report is to be made by May, 1910 (Do you hear me, Mr. Harrison)?

The present hearing is not a suitable occasion for extended discussion of the sanitary aspects of the Passaic Valley sewer, but this commission desires to make a few remarks upon the possible injuries which may result to navigation if the Passaic Valley project is carried out.

Although possessing certain novel features, the Passaic Valley project is not altogether new. Nearly thirteen years ago legislation was secured in New Jersey looking to a general system of sewerage for the sanitary improvement of the Passaic Valley, and this project has been urged in some form ever since. For the last seven years, at least, it has been proposed to collect all the sewage of the Passaic Valley district and discharge it without purification into New York harbor. The question whether injury would be done to the harbor if the Passaic Valley sewer was allowed to discharge crude sewage into these waters has been the subject of several investiga-
92 tions. In 1903 the Passaic Valley Commission was required by the New Jersey legislature to investigate whether the proposed outfall was likely to cause a nuisance to persons or property within the State of New York. On that occasion favorable reports were secured from a number of prominent engineers and, with the advice of the Attorney General and Governor of New Jersey the project was allowed to proceed.

Earlier than this the Harbor Line Board made an inquiry as to whether the discharge of the sewage would injure navigation. At that time it was proposed to discharge the sewage of the Passaic Valley into Newark Bay at a point about twenty-two hundred feet above the bridge of the Central Railroad of New Jersey. The Board examined this project and made an adverse report upon it under date of May 28, 1897. The Board summarized its opinion in the following words: "It is easy to see that it will require only a few years to make the proposed sewer system not only a public nuisance but a serious obstruction to the navigable waters adjacent to the harbor of New York."

In 1903 the Legislature of the State of New York created the New Yark Bay Pollution Commission to investigate the threatened pollution of the waters of New York Bay and vicinity. One of the recommendations of the Pollution Commission is especially worthy of attention at this hearing. The Pollution Commission protested against the execution of the plan to discharge the crude sewage of the Passaic Valley into New York bay and advised the Governor of New York that in the event of the Passaic Valley Commissioners
93 pressing the construction of their works, action be brought in the Supreme Court of the United States against the State of New Jersey and the Passaic Valley District Sewerage Commissioners.

So far as the proposed plan for diffusing the Passaic Valley sewage through the tidal waters can be comprehended, it gives inadequate assurance that the sewage will be immediately diffused and

dispersed. Diffusion and dispersion are phenomena which, as related to the discharge of sewage into harbor waters, are not sufficiently understood to be within the range of exact engineering control. Experience shows that the discharge of large volumes of sewage into a natural body of water generally produces evil consequences in the vicinity and that the extent of these evils increases more rapidly than the quantity of sewage.

The Passaic Valley scheme bears a certain resemblance to works which carry the sewage of Boston and its neighboring municipalities into Boston harbor, and it is understood that the experience of Boston has guided the Passaic Valley Commissioners in making their plans. Having visited Boston and seen the outfalls in that vicinity the Metropolitan Sewerage Commission has no hesitancy in expressing the opinion that the conditions in Boston harbor should not be duplicated in New York bay.

Freedom from evil effects cannot be urged on the ground that grit and large solid particles will be removed before the sewage is discharged. The amount of harm which might result would not be confined to the channels near the sewer outfall. In places
94 remote from the mouths of sewers the bottom of New York harbor is already covered with accumulations of fine black material which it has been impossible to distinguish from sewage sludge. The United States Government has removed thousands of cubic yards of this material from Ambrose Channel.

The evil results which would follow the deposit of sewage matters in the channels would not be restricted to the mere cost of dredging. The interference which vessels might experience from the presence of dredging machines should also be considered. In this connection it should be remembered that the proposed outfall works would be located in the land-locked part of the harbor on the edge of the main ship channel, and consequently in the direct path of vessels bound in and out of New York, Newark Bay, the Kill van Kull and close to the path of the Municipal ferry between Manhattan and Staten Islands.

The need of affording adequate sewerage facilities for the rapidly growing municipalities in the vicinity of New York City, and the importance of keeping the river tributaries clean are fully recognized by the Metropolitan Sewerage Commission. But the practice of sanitating inland municipalities at the expense of the harbor is unwise. There is a limit to the quantity of filth which these waters will tolerate and which the public will consent to have floating about. Investigation has shown that portions of the harbor already receive sewage in excess of their capacity to assimilate in a harmless and inoffensive manner. It is the opinion of the Metropolitan
95 Sewerage Commission that the discharge of sewage into these waters should be restricted to such municipalities and districts adjacent to the bay as cannot otherwise dispose of their sewage except at prohibitive cost.

The present project of the Passaic Valley Commissioners is not the only practicable way of handling the sewage of the Passaic Val-

ley. It is feasible to purify the sewage of the twenty or more municipalities concerned by public works constructed for that purpose. The cost of constructing and operating works to purify the sewage of the whole Passaic Valley would not be materially greater than the cost of constructing and operating the works under the plans proposed, with their grit chambers, screens, pumping station and large tunnel under Newark Bay, the Bayonne Peninsula and New York bay. If such purifying works were built a harmless and inoffensive effluent could be discharged into Newark bay in place of discharging the raw sewage as now proposed in a more or less putrefying condition into New York bay.

It is the opinion of the Metropolitan Sewerage Commission that the discharge of sewage in the manner and in the quantities proposed by the Passaic Valley Sewerage Commissioners would be detrimental to the interests of navigation and that this project should be opposed by all who desire to see New York harbor maintained in a clean and unobstructed condition.

Mr. Dean: Dr. Porter, the State Commissioner of Health——

Col. Knight: Before Dr. Porter speaks,—Mr. Soper, you
96 spoke of some parts of New York bay being already polluted to the limit—have you those in mind?

Dr. Soper: I am speaking of Gowanus Canal and Newtown Creek.

Col. Knight: You would not consider those as exemplifying the general condition of affairs around New York Harbor?

Dr. Soper: The general condition, no.

Col. Knight: A special case?

Dr. Soper: Yes.

Col. Knight: And, in the case of Gowanus, do you notice any perceptible difference in the condition there as you go from the head of the Canal down to the mouth of it?

Dr. Soper: There is no very material difference until you get to the Bay.

Col. Knight: But you will admit that at the Bay the relative percentage of trouble—if I may so call it—is very materially reduced?

Dr. Soper: It is reduced, but it is difficult to say whether materially or not.

Col. Knight: But you are able to determine that?

Dr. Soper: Contrary to what has been said this morning, there are no standard sewerages.

Col. Knight: Then how are you going to pass on the question of pollution, if you have no standards?

Dr. Soper: To fix the sanitary standards of the harbor
97 for all time, is too much to do, or what the tide will do or the water permit; it is not necessary to-day to call people outright falsifiers——

Col. Knight: We are not talking about calling people names. When you say there are no standards,—what do you propose, yourself, your Board, to be governed by; where does the limit of pollution rest? You say it has been reached in certain localities in New York Harbor, and then you say there is no standard?

Dr. Soper: To answer you directly, we will include the Passaic River as one case in which the sense of the public of its odor has established a standard.

Col. Knight: Then your standard is that of the nose?

Dr. Soper: Of the nose, and of the eyes, and of the public health and of other considerations——

Col. Knight: But nothing definite?

Dr. Soper: This Metropolitan Sewerage Commission that exists to-day and which I represent as one of its members, has for one of its undertakings to come as near establishing a standard—a sanitary standard for New York bay as is practical——

Col. Knight: But you do not admit that anything exists to-day as a standard?

Dr. Soper: Not that can be stated in mathematical terms; no.

Col. Knight: Well, that can be used, practically, for de-
98 termining whether the discharge of this sewage will pollute the waters of New York Bay?

Dr. Soper: We believe that the condition of the waters in Boston Harbor could be instanced as a good criterion.

Col. Knight: How are you going to apply the conditions of Boston harbor, practically, to New York harbor?

Dr. Soper: Boston harbor—there is a project proposed here which seems likely to produce the same conditions as in Boston, or worse, and we object to those conditions; we think that that is a practical application.

Col. Knight: You think that by developing or appropriating the Boston methods, either or both, is going in the wrong direction?

Dr. Soper: We do.

Col. Knight: But you have no standard or standards to measure by, as to whether that is wrong or right?

Dr. Soper: Not as yet.

Dr. Porter: My main object in appearing before you this afternoon is to state to you what the policy of New York, so far as the State Department of Health is concerned, is, regarding the pollution of the streams and of the waters of our State.

I believe that the discharge of raw sewage into the waters of this, or any other, State indicates a defective civilization.

I believe that the progress of science has been such and the
99 progress of our health experience has been such that we are no longer justified in polluting deliberately and with full knowledge of the consequences that may result, the waters of New York harbor or of any other harbor or of any other waters, where it is possible to purify this sewage before it is introduced into those waters, and I withhold permission whenever it is asked of the Department, and have taken steps to prevent or remove such conditions.

(Reading:) "In appearing here to-day in opposition to this Passaic Valley project, I wish to be clearly understood as in no way intending to oppose, nor obstruct, any great and needed sanitary measure. On the contrary, I am here to oppose only the execution of a project that may not carry with it the fullest assurance that the

benefits to be secured will be realized in a manner that will not give rise to objectionable conditions—whether from objectionable deposits, offensive odors and appearance, or injury to health.

In approaching then the question at issue—the pollution of the tidal waters of New York bay—I believe that it will be both wise and profitable to consider the question from the most general and comprehensive viewpoint; to consider the Metropolitan District as a whole, including the municipalities of both States; to weigh the question involved with respect to the needs of the entire district, before stating any conclusions or giving a decision in any particular case. The need of this comprehensive viewpoint and reservation of decision seems to be particularly emphasized at this time in view of the fact that we are now beginning to realize with greater force the extent and effect of present pollution upon the waters of the
100 harbor. Furthermore, the study of this whole question, as you know, has been entrusted by the State of New York to an Investigating Board, which has been studying this problem for some time and which it is expected will, within a reasonably short time, report the necessary information that will enable not only your Board, but others entrusted with corresponding duties, to consider intelligently and act safely in regard to it.

To give a decision in advance of such knowledge would, in my opinion, certainly be a step in the wrong direction.

The importance of any evil consequences that might arise from the proposed discharge of sewage from the Passaic Valley District into New York Bay can hardly be over-estimated. They would affect not alone the people of New York City but the cities and communities along the New Jersey shore as well. They would involve not only the comfort, health and life of these communities, but would also affect vast industries such as commerce, shell fisheries and others. It is, in fact, because the questions involve the health, comfort and welfare of the citizens of this State that the State Department of Health is particularly interested, and wishes to appear here to appeal to you for cooperation in conserving its policy in preventing a further pollution of the waters of the State.

The policy of the Department during the present administration has, I believe, been so fully and repeatedly expressed that it is by this time fairly well understood throughout the State. Briefly
101 expressed, this policy is in opposition to the further pollution of the waters of the State, whether inland or tidal, in all cases where such pollution may appreciably affect the purity of these waters. In accordance with it, the State Department of Health has during the past four years used every effort to remove existing pollution and restrict the discharge of additional sewage into our streams and tidal waters.

Owing to territorial jurisdiction in this matter, the plans for this project have not so far come before me, either officially or informally, and I am, therefore, not in a position to speak with any degree of authority as to the proposition as a whole or in detail. I am informed, however, that the plan of the Passaic Valley Sewerage Commission is to collect the sewage of about one and a half millions

inhabitants of New Jersey municipalities lying along the Passaic River in a large trunk sewer some twenty-six miles long, and to discharge it into Lower New York Bay in the vicinity of Robbins' Reef Light. As to what methods will be used to purify this vast amount of sewage, or as to the conditions under which it will be discharged at the outlet, or as to the effect of the discharge of this large volume of sewage, at the proposed single outlet, upon the waters of the harbor and the health and comfort of the people, are questions which are of vital importance, but about which the people of New York have not as yet received positive information or assurance.

Judging from the report of the advisory engineers, how-102 ever, it would appear that they recommend, and we are accordingly led to believe that it is the intention of the New Jersey authorities to provide, only a partial purification of this large volume of sewage. According to these engineers, it is proposed to construct upon the Newark Meadows a grit or sedimentation chamber and provide mechanical screens for removal of the coarser or grosser solids, and to provide at the outlet near Robbins Reef some six miles from shore, and at edge of the main channel, a system of multiple outlets submerged some forty feet below the surface, distributed over what they term a dispersion area.

There would seem to be little doubt that this method of disposal, compared with the present method in vogue in New York, where sewage is discharged without settlement or screening at pier and bulkhead lines, near the surface of the water, is relatively superior, judged from the standpoint of methods. As to the absolute efficiency of the method, under the conditions which it is proposed to discharge this sewage, it is not so clear. One thing we are certain about, and that is the inadequacy of the present method of disposal in New York City, which is apparent to any careful observer who inspects the condition of sewage pollution along the shores of Manhattan, and for a considerable distance above and below the city. It is true that the proposed volume of sewage from the Passaic Valley trunk sewer may be small compared with present or future volume of sewage from Greater New York—perhaps only ten per cent.—but have we sufficient knowledge at this time to be assured that this volume of sewage discharged with only clarification 103 within the limited dispersion area proposed will not become in any way objectionable?

Viewing this question broadly, and in the light of what we do know as to efficient methods of sewage disposal, we can state with little doubt that there are methods of disposal by purification which are not only more efficient, but probably no more costly, than the method of disposal such as that proposed for the Passaic Valley District. The experience and successful practice in both this country and abroad fully bear out this statement. And, if this be so, it would seem that such methods of purification might better have been adopted, or at least proposed, as an alternative proposition.

I believe, therefore, that in view of what I have said, that it is your duty, and I would urge it upon you, that you give the most careful consideration to this project, and judge it not only in the light of the more restricted question of the silting up of the harbor

but also in the light of the sanitary questions involved. I trust that in doing this you will bear in mind the policy of the State Department of Health in reference to the protection of the waters of the State from pollution, and the fact that in matters pertaining to stream pollution the trend of public opinion and views of sanitarians is towards higher standards of purity. Finally, I would urge in this matter, that you withhold your approval of this project until such full information is furnished by the New Jersey authorities as to the methods of purification they propose to adopt; and that
104 you withhold your approval unless you are assured that these methods will safely dispose of this sewage without danger of offense, or injury to health, or damage to the many and important interests which are at stake."

Col. Knight: Have you not any definite information to give about those more efficient methods? What would you advise?

Dr. Porter: The methods employed, for example, at Saratoga, New York, by sedimentation, by septic tanks, by rapid contact beds made of coke, in fact, a dozen methods.

Col. Knight: You certainly give credit to Mr. Hering of being familiar with those methods?

Dr. Porter: No doubt at all.

Col. Knight: Generally, you do not consider his recommendations as made seem in accordance with the results obtainable by those methods?

Dr. Porter: No, sir.

Col. Knight: You claim that those are more efficient than are the methods he recommends?

Dr. Porter: I do not know that he has recommended any method for purifying the sewage,—as I understand it, he does not believe that the purification of the sewage is necessary——

Col. Knight: You would say that he recommends clarifying rather than purifying?

Dr. Porter: Yes, sir; he recommends clarifying, rather than purifying.

Dr. Darlington: Colonel Lockwood, and Gentlemen of the
105 Commission: One of the gentlemen who spoke in favor of the application, brought up a certain legal question; I did not know whether that would be brought up this morning or not, and all that I wish to say are two or three words. I presume that you are all familiar with the legal aspect of the jurisdiction over the waters of New York harbor, but at the same time I desire to call your attention to the fact that the laws have set down that the State of New York shall have and enjoy exclusive jurisdiction, as to quarantine, over all of the waters of the Bay of New York and Hudson river, and, still further, that the State of New York has also jurisdiction over the wharves and docks and shores and land and over the vessels and crews, and that vessels shall be stopped and quarantined, and laws in relation to passengers, and so on,—in other words, the law gives jurisdiction beyond the State of New York; that the State of New York and the City of New York has jurisdiction over the health of the harbor, and I recently received a decision

from the Treasury Department on that question relative to something along that line——

Mr. Riker: May I be allowed to interrupt for a moment? Does the Board propose to hear argument? We did not understand that this Board would hear legal argument——

The Chairman: We will leave that out——

Dr. Darlington: We will leave that out, but, let me say that, on account of having jurisdiction, the Department of Health of the City of New York would certainly exercise the jurisdiction
106 of the City of New York should they attempt to commence to build; it is not a case of waiting, as one gentlemen spoke of as being the practice in equity, until we could prove the existence of a nuisance——

Col. Knight: I do not understand that any permit from the War Department would prevent you from commencing to act——

Dr. Darlington: If I understand correctly, the Harbor Line Board was not created to give permission for encroachments upon the harbor, but to prevent encroachment——

The Chairman: The question of jurisdiction is not now before us; we would not pass upon the question of jurisdiction; this hearing is to ascertain and report concerning the matters set forth in the statement of the Chief of Engineers on the application——

Dr. Darlington: I simply wish to state, then, in regard to some of the arguments that have been raised,—I would like to say that this supervision, which is vested in the City of New York, over the outlets of the harbor, would be exercised.

I would like to ask this question, which they might answer at some future time; as to who is to supervise this sedimentation and screening? Will they permit officials of the State of New York to supervise those operations? Can the officers of the City of New York see that it is properly done?

The Chairman: That is a fair question for you to settle with them.

Dr. Darlington: And, also, if it be true that the paint comes
107 off the houses along the line of the Passaic River, what are we to assume but that after it reaches the Bay it will do the same to the vessels——

Col. Knight: It certainly will, if it is in the same condition——

Dr. Darlington: It is not claimed that they intend to purify it, but still, as the arguments seem to be very thick, by the engineers, who have not been able to say or determine definitely anything about it,—as this seems to be largely an experiment, why do not they let the first sewer of this kind, as proposed by the State of New Jersey run down and empty opposite Long Branch, Asbury Park, or some of the other New Jersey resorts, and see whether, in front of their own lands, it does any damage or harm?

As a general proposition, sewage is unsanitary, and the pollution of water by sewage is unsanitary, and if it is intended to increase the pollution of the water in New York Harbor by means of this new sewage system from New Jersey towns, a heavy burden of proof rests upon the persons who propose this increase of pollution, to show that it will do no harm.

I desire to submit that the burden of proof does not rest upon the City of New York, but upon the State of New Jersey, and that if there is any question of doubt in the minds of this Board, any doubt whatsoever, they are not at liberty to simply pass judgment upon it, but that they must decide upon the side of safety. This is a general principle in all public health work.

108 The time has passed when it is necessary to show that a condition produces pestilence in order to be a nuisance and require correction. The standards of hygiene and of public decency are continually becoming higher. What was permitted twenty years ago is not to be tolerated to-day, and what is tolerated to-day will, in all probability, not be permissible twenty years hence. The fact, therefore, even of noxious and disagreeable odors must be taken into consideration, under the laws of the State of New York. Nay, more, there is large flotsam in the water, and even to-day driftwood which is polluted by excrementatious material is being carried into the houses of tenements,—people pick up this fire-wood, covered with excrementatious matter and take it home. We believe we have traced many cases of typhoid fever to the condition of the flotsam in New York bay.

The Metropolitan Sewage Commission was created to formulate a policy of sewage disposal for the whole metropolitan district, and, in due course, that will be done. How can we ever create better conditions if we allow these things to come in here now, as proposed by this application? The Metropolitan Sewerage Commission has already registered its opinion against the Passaic Valley project, and has enunciated the principle that large volumes of raw sewage from municipalities not on the shores of the harbor should not be discharged into these waters. It has come to my knowledge that the Commission has knowledge of many facts bearing directly upon

109 the sanitary side of the question which at present they evidently do not feel at liberty to put forward: Therefore, I think it will be better to let this application wait until some of those questions are settled.

Not only must we think of the condition when these great works are first put into operation with six hundred thousand people contributing sewage, but what will occur, let us say, in 1940, (and we must also take into consideration the suspended material which comes from streets and roads of that kind, which, on account of the streets not being paved in those country districts, come under the New York City standard) and subsequently, when the waste of one million, six hundred thousand people would probably be flowing out at that point.

The persistence with which these people, who are interested, endeavor to carry out their project, means that the people of the State of New Jersey do not care whether the harbor of New York be clean or otherwise.

The one reason above all others, it seems to me, why New York to-day is a great commercial center, is because of its efficient quarantine. If it were not for that, we would not have the commerce we enjoy. Let any great plague or pestilential disease become epidemic

in the City of New York through laxity of its health officials or the quarantine and I ask you, what would become of the commerce here? Why is it that New Orleans, with its splendid geographical position at the mouth of a great river, over which freight may be carried at a minimum expense, is not the greatest commercial center? Simply because of its history in the past with its relation to yellow fever. That is why I am here to-day. We are very jealous of health and quarantine regulations as it affects our commerce, and unless it can be proven absolutely that no nuisance whatever will be created in any way, shape or manner, the burden of proof resting upon the people who endeavor to build this work, we do not believe that they should be at liberty to undertake the work, and that you gentlemen, and all others in authority, should take the safe position, and prevent it.

Col. Knight: When that sewer was proposed to be built above Newark, at Passaic, the court did not take that position?

Dr. Darlington: I do not know with regard to that case.

Col. Knight: There the court said that they could not bring a suit to prevent the nuisance, but you must prove the existence of a nuisance, which you are going to prevent.

Dr. Darlington: We prevent nuisances before they are created in this City; we prove that the conditions would create the nuisance, and prevent its creation.

Col. Roessler: You represent the Health Department of the City of New York?

Dr. Darlington: I do.

Col. Roessler: The gentleman who preceded you referred to a State law which aimed to prevent the pollution of all streams navigable and non-navigable; that applies, of course, to New York Harbor?

Dr. Darlington: Yes, sir.

Col. Roessler: It applies to Newtown Creek, that we all know to be polluted?

Dr. Darlington: Yes.

Col. Roessler: Has anything been done to abate the nuisance there, under that law?

Dr. Darlington: Yes; things have been investigated looking towards the abatement of conditions there, by the Department of Health of New York City; we will not permit slaughter houses to dump blood or refuse; we make them keep out. We are endeavoring to correct that condition, but we are waiting until we can have the report of the Metropolitan Sewerage Commission, which is to be rendered in 1910. We have corrected many of the evils, but we cannot correct them unless we can stop sewers of this kind from being allowed to enter the harbor. Daily we find cases where we can trace typhoid fever—as near as you can trace anything of that kind, to people bathing in the waters of the Bay, and we will not permit the baths to be located off pierhead sewers to-day,—the Department of Health stops those permits.

Col. Roessler: And has any plan been formulated, tentatively even, that will prevent those obnoxious sewers entering those streams

along North Bay? Has anything been done looking to having that effluent cared for or purified in some way before it enters into the harbor of New York?

Dr. Darlington: Not as yet.

Col. Roessler: Is it contemplated?

112 Dr. Darlington: Yes; it is contemplated.

Col. Roessler: Will you please state what is contemplated?

Dr. Darlington: That belongs to the Metropolitan Sewerage Commission.

Mr. Dean: I am familiar with the law on the subject and I will take it up later on.

Dr. Darlington: It is contemplated; I do not know what methods will be employed.

Col. Roessler: I do not know that that has any special bearing on the question before us, but inasmuch as the matter has come up I thought it seemed just as well to inquire concerning it.

Dr. Darlington: There is one other point raised by the applicants, that I wish to speak of. It was spoken of, about the City of Hamburg having cholera within it, and Altona although using the same water—of the river Elbe—into which the sewage of Hamburg was discharged, not having the cholera within its borders except cases where water had been drunk in Hamburg. Now the reason why cholera was in Hamburg was simply because it drank its own pollution; the reason why Altona did not have it was because their drinking water was filtered. Filtration takes out the bacteria. On the question of bacteria, we have been able to trace that water acts—operates chemically on suspended matter or bacteria in coming over a long distance, to a certain extent, and bacteria are by this action to an extent eliminated.—it takes a long distance. Now, the

113 Croton water shed is comparatively free from nuisances, the lakes and streams or most of them have been acquired, and the edges of the streams have been acquired, and sewers diverted, and everything, yet in the City of New York I can find the colon bacillus, right in the waters which have been thus safeguarded, in the City of New York.

Col. Knight: We are not proposing to use the waters of the Hudson river for drinking purposes; that is used for cleansing the streets and for fire purposes.

Dr. Darlington: But people put their hands into it, they wash their hands in it, and bathe in it; and it mingles with the dust in the streets, and we have, we believe traced cases of typhoid fever to this very source of flushing the streets with that water, and we think the streets and the City would be better off without it.

(The hour of 1.35 p. m. having arrived, the Chairman announced a recess until 2 p. m.)

(After recess—2.10 p. m.)

The Chairman: The gentlemen will come to order, please.

I want to say that it is the sense of the Board that it is not proper or necessary to hear anything in regard to the law features of this

situation, for the reason that the Secretary of War, if he should grant a permit, merely withdraws the objections of the War Department, but confers no legal rights: What we do want to hear is with regard to the matters affecting the question of navigation.

Mr. Higgins: Mr. Chairman and Gentlemen of the Board,
114 I come here representing the Chamber of Commerce of the City of New York who, I think I can make the assertion without fear of contradiction, are a disinterested body of men in the City of New York—the most disinterested body of men in the City of New York, and I want to make this emphatic because I come here with the most intense spirit on the part of the Chamber, in opposition to this movement, and, therefore, I make the assertion in the first person and say to you that they feel it is necessary to raise these questions upon this application; and those gentlemen have no motive of their own to consider; they are trying to do exact justice to the world, and their sympathies are with you in every way; there is nothing you undergo or suffer in your community over there that is not regretted, but what we sympathize with you.

Now, gentlemen, there are certain important facts I must remind you of. The City of New York cannot preserve her commerce unless she preserves absolutely her condition of a perfectly safe port, a safe port for vessels to visit and for passengers to land to carry on their transactions in the City of New York. Now, it must be remembered that the commerce of the City of New York represents almost the great bulk of the foreign commerce of the United States, and you can see how very important a matter it is to all the citizens, not only to the citizens of the City of New York, but to the whole citizenship of the United States.

I represent both the Committee on Harbor, and the Com-
115 mittee on Foreign Commerce. I am the Chairman of the Commitee on Harbor and Shipping, and Mr. Shweppe, who is chairman of the Committee on Foreign Commerce, requested me to make my appearance in his behalf.

Now, there are certain features about the harbor of New York that I am very certain very few people know. I am one that does know. I am the President of the Board of Pilots, and from that Board I learn facts, and they have assured me that there is a strange natural phenomenon in this harbor; that there is a body of water, between about Yonkers and just southerly of Robbins Reef which simply oscillates backwards and forwards and never reaches the ocean. Now, that is a very strange fact, and they have studied it mathematically. One of them told me only yesterday that he had stood on the shore near Governors Island and had noticed a barrel go backwards and forwards in this current, down to near Sandy Hook and back, it returned eight times without losing sight of it—eight times—that shows the return of the barrel in the tide; it was a proof to him of the fact he had stated to me, which was that this body of water oscillates back and forth and never reaches the ocean, and it is therefore the source of the deposit in the harbor, whot is true of the barrel is true in respect to anything the water contains, and it is therefore the source of the deposit which is

made in the harbor and that deposit to-day is apparent in many respects; it has compelled the Government to look for a channel through the Bay to provide for the vessels coming into New
116 York harbor, and the Government located Ambrose Channel; Ambrose Channel was built at a great expense, and to-day Ambrose Channel is threatened by this operation of the tide, and when that tide comes back it drives this whole body of water up in the direction of the different piers and docks around Staten Island, a lot comes up into Newark Bay, and so this operation goes on.

Now, therefore, when you make your calculations to discharge this sewerage right at the point where this oscillation takes place, and calculate that it is going to produce a self-clearing operation by itself, I want to warn you that it is not possible.

Now, in regard to foreign commerce, you should all know that if there should be an epidemic break out and it should be traced to any location of a sewage outfall in that lower harbor, and this great discharge of sewerage should produce in the atmosphere pollution and sickness there, do you gentlemen know what the effect would be? It would be so disastrous on the commerce of New York that it would be a long time before we could get over it.

Therefore, the Chamber of Commerce is vitally opposed to increasing the deposit of sewage in New York harbor for any reason or from any source. We find that the Health Officers of the State have considered the condition of the harbor and it is now so perilous that they have established this Commission of which you heard from my friend, Dr. Soper, who is the Chairman of that Commission. And that Commission was appointed with a view to
117 seeing whether New York herself could not reduce the deposit of the sewerage which she is compelled to put in these waters at the present time by reason of her position. Therefore, this is no trifling matter. It is a matter of the very greatest important. And I saw that, in the first application which was made to you, they admit there, they offer, I think, if I remember correctly, they offer to pay for the cost of dredging which may be the result of the injection of this deposit into the harbor; that is an admission on their part that the deposit is going to take place from it, and I consider that it cannot be avoided, and the deposit will necessarily take place, and that deposit must spread itself more or less into the channel. This place of deposit is right at the head of one of the main channels that go in and out of the harbor and any deposit that takes place there will tend to encroach upon and deposit in our great new channel, Ambrose Channel, as it is called, which is an absolute necessity to accommodate these great large ships which come here and bring to us the remarkable and fruitful results in money and passengers and freight shipments.

And my object is to simply repeat to you that the Chamber of Commerce places the utmost confidence in your Commission; they feel that you are going to examine this matter carefully, conscientiously and with the full view of the future and of the facts; that what you are authorized to do is to object to any action which has

for its possibilities a deposit to injure the channel, or any other injurious effect upon the City and Harbor of New York.

118 We therefore look to you with great confidence, that you will examine every fact connected with it, and that in your report, if you will join us in the view that it is not to be granted, you will undoubtedly make such a report to the Secretary of War. Other than that, of course, it remains to be opened to examination from time to time.

One of the greatest difficulties with such an enterprise as this is this: These gentlemen indicate to you all their precautions by which they hope to do away with the evil effects of this pollution, and yet, when you have given them the permission to create the plant and to adopt the measures which they wish to do, there is no possible way you can get your remedy. What are you going to do if you find that it does not operate as they wish and deposits do take place and are reported upon. You cannot make them undo it and destroy this great thing which is going to cost a number of million dollars.

Now then, before you grant the request, if there is a possibility of its coming out or going that way, you are incurring a fearful risk for the City of New York, and, therefore, I must beg you most earnestly to examine that, and if you have any doubt, that doubt should be on the side of the contrary view of the whole subject,—it should be denied.

I approached this meeting with a positive conviction, after reading a history of the different processes adopted in Europe; that there

119 the question had become so very disagreeable that in the City of Milan,—a City, I think, of one hundred and fifty thousand inhabitants, the stenches were so great from the river that the people could not walk on the wharves with any pleasure.

Then, the City of Berlin adopted a most wonderful process, and the City now makes money on its sewerage. The water is drained off; the solid matter is expunged from it, and then put through a process and formed or made into cakes, and sold as a great fertilizer, with the result that the City is to-day in receipt of a larger interest—or of interest on a larger amount, greater than the whole cost of the plant, although it was a very costly plant. The same thing is taking place in the cities of England and elsewhere, and I feel, gentlemen, if you will examine into the various details and note the different steps which have been taken in Europe, you will find that there is a great variety of measures that can be adopted from which I fully believe these gentlemen can get their relief in some other form.

Col. Knight: Mr. Higgins, a very strong part of your remarks, or one very strong feature of your remarks, is that question of trying to prove from the barrel theory that this sewage will not find its way to the sea, but will oscillate up and down the waters of New York harbor.

Mr. Higgins: Yes; permit me,—I did not cite the barrel instance except as a curious fact, a fact which was told me yesterday by one who had watched the fact.

Col. Knight: That was to show that if that barrel never gets out

to sea, if it oscillates right up and down in the tidal current,
120 you would never get any of the deposit into Ambrose Channel?

Mr. Higgins: I beg your pardon; this was a surface test,—the deposit on the bottom could get into the channel in a variety of ways.

Col. Knight: When it comes to the deposit on the bottom, we find in a special report, that according to an analysis of the movement of the water in the harbor——

Mr. Higgins (interrupting): There is not one of them that can be relied on. I state emphatically what I know about the tides; what I have learned from my pilots, which is diametrically opposite to those analyses.

Col. Knight: I wish every argument of that sort could be so readily disposed of.

Mr. Conkling: If the Board please, I am the president of the Realty League of the City of New York, an association of property owners, chiefly in the Borough of Manhattan, for mutual protection, they meet periodically, and at the last meeting this thing comes before us. So, I appear as the trustee of several estates worth several million dollars.

This matter of the sewage is a very serious problem. I might call the attention of the Board to the City of Berlin, Germany, with a population of about two million, and the City of Birmingham, England, with a population of about five hundred thousand, or nearly as large as the population of this entire Passaic Valley. There, they have a large sewage farm, which solved this question very easily. Does the Board know about Tuxedo Park, in
121 Orange County? I suppose not. That is some thirty-five miles out; it is North of Paterson about twenty miles; there, the drainage of one hundred and ten cottages flows into a system of septic tanks, and screened, and treated and disposed of; the system has been in use there for twenty years, and there is no smell of any kind, not even the remotest character; I was there yesterday, and have been there in hot weather and cold weather, and there is never any smell at all from that sewage disposal plant. Then, there is the State Asylum, at Morris Plains, New York, about thirty miles from here; they have a sewage farm there about a half a mile from the hospital; Morris Plains has a population of two thousand at the present time; I was there a hot day some time ago and there was no smell from the sewage farm whatever, only a half mile off, on a hot day.

Instead of polluting our Bay here by this sewage, there is some other method of doing it. As a New York man I should not say what, but perhaps the Hackensack meadows would do for the location of the sewage disposal plant. I crossed them yesterday, and didn't see a house for several miles, and if they can have a sewage farm within half a mile of Morris Plains, there seems no reason why they could not have this kind of a plant there on the Meadows and no one would be bothered by any smell; they could have a purification, filtration, clarification or any other "ation" necessary and put the stuff in such shape that the water could be discharged into

the Hackensack or Newark Bay without any damage to the Harbor.

122 Mr. Harrison said, I think, at least one of the speakers, that it would be more expensive to have a sewage farm or sewage area than to build the proposed trunk sewer: Aye, gentlemen of the Board, there's the rub! More expensive! The four million people of Greater New York must not suffer for six hundred thousand in the Passaic Valley!

I regret my duty calls upon me to oppose this scheme; but it will not do! We cannot stand it! Our interests are too large here. This Association which I represent owns property in the Borough of Manhattan alone worth about Two hundred million dollars. That is a great interest to have in real estate, and we claim that our stores, our houses, our theatres would be damaged by this proposed sewer. If the Board might like, I will submit to you a written statement in regard to the matter. I thank you for your attention. I am ready to answer any questions on behalf of the property owners as to our interests, our warehouses, our stores, our wharves.

Mr. Monk: Mr. Chairman and Gentlemen: This is a subject, Mr. Chairman and Gentlemen, that I have studied and practiced for nearly fifty years in New York City. With almost sixty years of experience around this harbor, and, with no offense to the gentlemen who represent New Jersey here in this application, I do not think, Mr. Chairman and Gentlemen, if they knew the sewage conditions of this harbor they would make that application.

I represent to-day, gentlemen, the Taxpayers of the upper part of the City and from Kingsbridge to Ward's Island on the Har-

123 lem River, from Ward's Island to Sandy Hook and from Yonkers to Staten Island take the Jersey Coast to Tappan Bay,—that forms the tide of the Hudson and on this tide flows the sewerage on the New York side of the Bay, on the New York side,—the New York shore. That forms the bank of sewage, of solid deposits on the New York side and New York City, and around the New York shore.

Take the average soundings in 1893 from the pier at the foot of 42nd Street North River to Pier 11 East River, on the 16th day of May, 1893,—the soundings on the heads of those piers was twenty-six foot of water, and on the seventh day of March of the following year the soundings were nineteen feet; two-thirds of that raise was caused by the sewerage from the bulkheads under the piers.

To give you another idea of the amount of sewage that is discharged, take the piers of the East River, with their box sewers, the plank they run on the brick work of the bulkhead,—those are supposed to convey the solid stuff and the soft sewage into the tide waters, but it does nothing of the kind. Those piers are vast piles of it that is not carried away, and they open the bulkheads and let it out.

I have been reading of the sewage being discharged in the tide water; it is discharged into the bulkhead, and, to give you some idea of the cost, the City paid in the year 1903, the sum of Seven hundred and thirteen thousand dollars to a few concerns in the City to

dredge the bulkheads to fourteen feet of water on the East River.

124 Now, gentlemen, take it around from Astoria, Long Island City, Greenpoint, Williamsburgh and Brooklyn, the hundreds of sewers, all the number of them, and the way they are discharging into this river, not taking account of what is discharged from the sewers on the New York side of the East River, and look at the condition of the water here at very low tide (referring to map). Go from there to Harlem, from Ward's Island to Kingsbridge, and it is really disgraceful to the City of New York to see the condition of that water.

I remember the time, gentlemen, when you could go in twelve feet of water and you could see the pebbles on the bottom of this river. You cannot do it to-day, and it is only possible by keeping a dredging machine going almost steadily over opposite Jersey City, to Robbins Reef, Spring, Summer and Fall, to keep a channel in so much water so that the vessels can get up to their piers. Those are the evils where the solids are discharged and it does not get beyond the pierhead.

Now, gentlemen, I would not advance this argument in opposition to the views of the gentlemen from Jersey only I know that other means can be adopted to discharge the sewage, and not South of the lower Bay, close to the tide water. As the gentleman remarked here that the sewerage can be discharged at a depth of forty feet, why not discharge it in a reservoir and pump forty feet of water up into the reservoir, by a stationary pump, and treat it there and

125 discharge it by land, over land, at ebb tide, and have the openings closed so that none of the discharge would go into the flood tide.

I intended to bring you, gentlemen, a design I had made, twenty years or more ago, for the purpose of conveying the sewerage of Jersey City to Gravesend Bay, and that sewer was to be able, according to the plans, to run paral-el with the East and North rivers, forming a combination sewer here below the Battery, with no discharge along the shoreline until we got to Gravesend Bay. Now, gentlemen, that means for all time. It don't mean for the present. Look at what is coming. Go back fifty years, with a population of three hundred and fifty thousand in New York City, and see where we are to-day. You are granting this permission for all time, and we all know that that harbor is not in condition even to-day to receive the sewage that is going into it. I beg of you, gentlemen, in the interest of the City of New York of which I am here as representing a part of it, that that application will not be recognized by any intelligent body of men.

Col. Knight: Will you kindly give us a little more detail about that sewer that was to go down to Gravesend and be discharged at Gravesend Bay? I do not care about the construction of it, I mean about the discharge into Gravesend Bay?

Mr. Monk: I designed the sewer, I think, twenty years ago; I also designed a sewer to take the place of our present box sewer, but because of the conditions here as to political affairs—

Col. Knight: I would like to know about the discharge—the details of the discharge into Gravesend Bay?

Mr. Monk: Those sewers were to be run in a parallel line—

Col. Knight: Never mind.—coming down to the mouth of it—

Mr. Monk: In to a parallel sewer,—the nearest point of discharge would be Gravesend Bay—nothing along the shore line: The nearest point there is, of course,—you take Bay Ridge—

Col. Knight: As I understand it, you were going to carry out this parallel sewer to be formed into a combined sewer below the Battery, and you were to carry out the sewage in this combination sewer, into a reservoir,—

Mr. Monk: And pump it out on the first of the ebb tide—

Col. Knight: Then you admit, from that, that the flood tide does no injury?

Mr. Monk: No, sir.

Col. Knight: How far will the flood tide carry this sewage?

Mr. Monk: From seven to nine miles.

Col. Knight: From seven to nine miles, that is the limit?

Mr. Monk: According to the way the wind blows there will sometimes be a difference amounting to a total of fourteen or fifteen miles.

Col. Knight: Never further than fourteen or fifteen miles under the most favorable circumstances?

Mr. Monk: Except when it gets into deeper water, beyond the action of the tide into the harbor. That is the object of most of these cities seeking to get their outfall beyond the tidal action.

Col. Knight: But did I understand then, that if all the effluent of this harbor were discharged at Gravesend Bay, it will not be carried back to the City, unless it be carried by the flood tide?

Mr. Monk: It will not be carried by the flood tide—

Col. Knight: You won't let it go out by the flood tide?

Mr. Monk: Yes, sir.

Col. Knight: The influence of the flood tide will only extend about seven miles unless there is a high wind and then double that distance at most, about fourteen?

Mr. Monk: Yes, sir.

Col. Knight: That would be the positive limit of any injury to the interests of the City by the tide carrying this sewage under those conditions?

Mr. Monk: So far as that is concerned, the tide, as it is in Boston—

Col. Knight: I am not talking about Boston, but here—

Mr. Monk: If you draw this (indicating) as the way the water goes the sewerage, I presume you will get some of it over here (indicating). If a pump, a stationary pump be placed opposite this reservoir—this reservoir is forty feet in the air, lifted up forty feet, and the sewage is discharged about an hour before the ebb tide, it will go through and it will not come back.

Col. Knight: Then, there is no reason, with these control gates that they propose on this application here, why they should not make

the discharge then, at the first of the ebb tide, and remove all your objection to the use of the sewer?

Mr. Monk: My good man, they would not get far enough off if the discharge is made in the harbor. Now, then, as I remarked, I designed a sewer, in place of the present box sewers and as I have given this matter considerable study, and inasmuch as I thought it my duty as a citizen and taxpayer of the City to come here to give you my views on certain facts, and I know that I am speaking facts here to-day as to the condition of this City and of New York harbor. The position of that harbor is most disgraceful. The odor that arises from low water from the first of June to the first of October is horrible, and to a measure due to bad laws and bad legislation. If the waters of the upper East River had been safeguarded fifty years ago, it would to-day be fifty feet wider—one hundred feet wider, but then you could not get the riparian owners to put in the proper sewers, if they had done that, instead of putting in the bulkhead sewers, they would have done something for the City, they would not have more water. And now, as you go through Little Hell Gate, and through the large gate and to the point about seven hundred feet beyond, where they are now building another large city, you will see what I refer to, and in thirty-five years from now the same will be true in Flushing Bay as you see here; and, again I ask you, gentlemen, as intelligent men, to study this question carefully before granting this application.

Mr. Colyer: Mr. H. R. Towne, President of the Merchants' Association, noted on your memorandum, has been unable to come and desires to have it understood that he would have been here under other circumstances.

Mr. Ring: Mr. Chairman and Members of the Board: I appear here as representing the New York Produce Exchange and I think I can also speak for other commercial bodies in the lower part of New York City. I think that the Produce Exchange has as large an interest in this matter as any other body of people in the City. We are located right at the lower end of New York, close to the water side; we have a large membership and a very large attendance; our offices are located in this section of the City and quite close to the point, or as near as any part of our City, to where this sewer is expected or intended to make its exit.

I come here, representing the Exchange, and enter our earnest protest against any permission being given to this sewer that is proposed by the Passaic company, simply because at the present time we empty our own sewage into the river is no reason why we should empty an additional quantity; on the contrary, as you have already been told to-day, measures are being taken or being considered whereby the sewage of New York City in course of time will be taken care of and will not be dumped into our bay and into our harbor. That time, I believe, is not very far in the future. It is a large subject. Of course, it is harder to remedy a thing than it is to make it right in the first place, but it will come.

Now, I wish to give you an illustration ofwhat can be done with a sewerage farm, and that I know of by my personal knowledge.

It has been stated here, I think, by one of the engineers, or at least one of the representatives of our New Jersey friends, that no system has as yet been discovered that will give perfect sewage sanitation and disposition. I take issue with him on that.

In 1889 I visited Australia and the City of Adelaide, a city of one hundred and fifty thousand inhabitants, had just incorporated a sewage farm. I was interested in it, naturally, and I visited the farm with some of the officials. It was located, as I recollect, about five miles outside of the City limits; a trunk line sewer conducted all of the sewage from the farm to this plant. The sewer, as it reached the plant, was taken up in large circular tanks and the water passed through certain sieves, that, I do not know what the substance was, but it took out all of the solid material; when I say all, I mean all absolutely, not a portion, and when it was taken out, that water came out just as clear as crystal, there was not a particle of sewage you could detect with the naked eye, and that water I saw, I looked at it and it was as clear as crystal, you could see it run through in the sewage ditches where it is taken out to irrigate the farms, and the water as I have said is as clear as crystal; no sewage in it. Now, as to the sanitation of it, how it is accomplished, I do not know, but by some chemical process or by the addition of some substance, it was rendered entirely sanitary and the material that was taken out was put into shape for fertilizing purposes, and it was distributed all over the farm; and I wish to point out to you that inside of four years that farm was quite self-supporting and was a revenue producer; that was in 1889, and it has continued so ever since, and there has never been a complaint of any kind.

Now, as to Melbourne, when I was there they had an epidemic of typhoid fever; I visited the city a number of times but quickly got out of it, whenever possible. The Yarra River was in a condition of similar at that time to what you say the Passaic River is now; it was crooked, dirty and smelt bad; it was a vile stream; the sewage was run into it and nobody wanted to be any nearer to it than anybody could possibly help. I arrived on a hot day, when to be near the river was almost over-powering. The epidemic of typhoid fever started the people to taking up the sewage system on lines the same as in Adelaide as might be necessary to be done. They bought property located within ten or fifteen miles of the City, and then Melbourne built a trunk sewer down to the farm, and inaugurated a similar system of sewage disposal to that at Adelaide, and only yesterday I talked with a gentleman from Melbourne, on this subject and he told me that the sewage farm was an absolute success; that it was a paying proposition; that it produced a revenue, that it purified the sewerage to such an extent that the water that came from it after it passed through this sewage process was absolutely clear and that it was not only clear but was so chemically pure that it could be drunk without any danger to any one, and that they sold the solid matter after treatment for fertilizer; which corresponded to what I saw when I was at the farm at Adelaide, and that same system, accordingly has been put in at Mel-

bourne and has worked admirably in both cities since. Now, I say that the United States or any city in these United States that cannot be up to modern ideas equal to those used away off in Australia is a pretty poor sort of a city, and, when the engineer or gentlemen comes here and says that no system has been ascertained or devised that has proven satisfactory, I take issue with him directly.

I wish to speak to you on another point. I come here as a practical steamship man, and have been in that business for many years. I know that the sewage from this City does fill up our harbor. We have loaded steamers at various piers here, and we know that whenever we have to go near a pier where there is a sewer that empties into it, that place has got to be dredged out every three or four years, and the steamers frequently run aground, and we are unable to unload them in such piers because there is not a sufficient depth of water and this is true not only in the official piers, but
133 privately owned piers, and we have dredged out many places for steamers to get out and not only that, but we have to wait for high water to get them to the piers. Take, for instance, along about Depew Street, Brooklyn, you cannot load steamers there drawing more than three or four feet, because of the large sewage deposits under which we labor at that pier.

I come here because of a double interest in this matter, and I do not think that simply because it is a matter of economy for the Passaic Valley boroughs, villages and cities, located in the Passaic Valley, that we should permit this imposition of emptying this sewage into our harbor when they can establish sewage plants there and can get rid of it. If the gentlemen think they can put the sewage into the condition they are going to and that in such a condition it will not cause a deposit or a nuisance, why not dump it into Newark Bay? We don't want it over here. If it is not a bad thing, let them keep it. We don't want it, and on behalf of the Produce Exchange of New York City, and I speak as a member of the Chamber of Commerce, I enter my strong protest against any permission being given to this scheme for sewage to enter into New York bay.

Captain Parsons: Somewhere about six years ago, the question of sewage was brought to the attention of our Maritime Association, of which I was at that time President, and we were informed then by the Metropolitan Sewerage Commission that, in twenty-five years, with the continuation of the same conditions which had
134 prevailed for the past few years that the harbor of New York would have reached the danger point for navigation from the sewage. One-quarter of that time has now passed, and we are that much nearer the danger-point, but we are nearer than that from the fact that the amount of sewage has increased in a greater proportion than previous to that time. I am here I suppose, to-day, to represent the sailing vessel interest more than any other one particular interest. I occupy a rather anomalous position, because I regret that I am here to oppose what New Jersey men feel as their interest, yet I am a New Jersey man myself, but I feel, Mr. Chairman, that no man, living along the Passaic Valley can divorce

himself from the best interest of the City of New York and of this harbor. The interests of the people living within fifty miles of this City are so closely allied with those who live here and do business here continually and are New Yorkers, that it is impossible to separate them, as no man can to-day in any way injure this harbor, if he is doing business in any way with the City of New York, without to some extent injuring himself. Therefore, I feel that the people who have charge of this sewage question would be unwise to make any arrangement incurring any extensive expense which would result in adding pollution to this already over-polluted harbor; but some method ought to be adopted, as has been suggested by the President of the Produce Exchange, my predecessor, to dispose of this sewage without injury to the harbor.

One of the gentlemen who has spoken since I came into
135 the room, said he had been familiar with this harbor for the last sixty years. I have a very distinct recollection that about sixty years ago the people dealing in fish in Washington Market were obliged to take their fish cars out of the slip from the fact that the water had become so polluted that the people who desired to eat fish in the market or buy fish from the market would not purchase them, feeling there was no assurance that while they might have come direct from sea, there was no assurance they had not come from those water-soaked, polluted fish cars, and consequently they were obliged to find some place for their cars where at least they were not in *side* of their patrons; and this was sixty years ago.

One of the points which we object to, those who, of us, are interested in the affairs of New York harbor, is that it affects the navigable capacity of the harbor, and it obstructs it, as has been alluded to by my predecessor, by filling up the heads of the piers, shoaling the slips, which are used for anchorages for small craft or vessels where the channels are in the strong and rapid flow of the tide, if the tide flows across the channels, as is frequently the case, then they fill up very rapidly with this sewage. It is also a detriment to the navigable capacity of the harbor from the fact that these bays, little arms of the sea, as they may be called, rather more than rivers, show pollution to such an extent that it is injurious to the vessels and their paint, both outside and inside, is so affected, that if a vessel
136 painted white be remaining in some of those waters would have become lead-color in a day and if there two or three days, nearly black. This has prevailed to such an extent that the yacht owners will not consent to send their vessels anywhere along the Brooklyn shore during the Summer season, as it implies an entire new coat of paint, and it is not only the outside that it affects, but stains the inside. The other point is that it is absolutely unhealthy for crews of vessels to remain on board while located in the territories or localities where this has been so offensive, and this is continually increasing.

I feel, therefore, that we, of the sailing vessel interests, and while the foreign sailing vessel interest is rapidly disappearing, yet we do have a large coastwise sailing-vessel interest which is worthy of some

2969

attention and some respect, and that the merchants who are doing business by using those sailing vessels are also interested in that which pertains to their welfare, and I do most seriously and sincerely trust that some arrangement will be made whereby this vast amount of sewage, which it is proposed to be emptied into the Hudson river out of the Passaic sewer, can be provided for in some other way.

Mr. Riker: I trust that Mr. Dean will be confined to questions which are directly relevant to this issue,—that is, whether the proposed work will interfere with navigation. One of the questions between the State of New York and the State of New Jersey is
137 whether it will be a nuisance, and I do not want the witnesses we are to use in that suit cross-examined on anything but what is relevant to matters of navigation.

Mr. Lebkuecher: If there is going to be some cross-examination, it seems to me that we might also with propriety ask the speakers on the other side in reference to some of their statements which they have made and which we think——

Col. Lockwood: I do not like the expression "cross-examination"; I think you had better "question" the witnesses or the speakers.

Mr. Lebkuecher: We think that some of their speakers also made some statements which will not be borne out by the facts.

Mr. Dean: I am perfectly willling to have the gentlemen we called or will call questioned by the gentleman representing the Passaic Commissioners. We have special witnesses here who have not yet spoken,—one is the Consulting Engineer of the State Board of Health, and experts on sanitary matters, generally informed on this subject of disposal plants, and it is with these gentlemen we expect to take up the technical side of the case for you, if you wish to go into it. Of course, the other gentlemen who have spoken, have spoken as representing various interests.

The Chairman: I take it that this asking of questions is for the purpose of furnishing the Board with more information, and I will say that to that extent and for that purpose the questions may be limited.

138 Mr. Riker: We most respectfully object to any questions being directed to the gentlemen who have presented the case for the Passaic Valley Sewerage Commission by any person other than the Chairman or members of the Board: We have produced the most eminent gentlemen; the gentlemen will be witnesses for the State of New Jersey in the litigation now pending between the States of New York and New Jersey and should not be questioned on matters involved in that suit except in the litigation of it. These gentlemen will be glad to answer any questions which this Board may ask. This gentleman, who represents, as I understand, theoretically, the State of New York, is the same gentleman who drew the bill that has been filed in the United States Supreme Court, and for him to go over our witnesses and ask questions which this Board do not want to ask, I think is eminently unfair.

Mr. Dean: I have no desire to get any other expert testimony from Messrs. Hering or Harrison if they will bring out plans in detail. I want to find out if there are any more definitive plans, any

better defined plan with reference to their proposal as to sedimentation, and screening, in order that we may be able to learn exactly what proportion of the solid matter they propose to remove, and how. They have stated that there will be no deposit, and that they intend to discharge the sewage in a liquid form and that it will be readily dispersed. If they will furnish us with specifications showing their definite plans for the accomplishment of these results——

139 Col. Knight: I might say that there are no definite plans; there is no use questioning for definition of plans. You can see from their application just what the specifications are which we have before us.

Mr. Dean: That is what we are after. They have not furnished specifications, although we have been endeavoring to learn from them what they propose to do, we have not been able to get any information. We want to learn the proportion of the solid matter, and the matter in suspension they propose to remove, and how it is to be done. We want to find out the size of their sedimentation tanks, the size of the screen; and they have not, as I have said, furnished this information; therefore, I have desired to question them in order to ascertain just what their application is for, with a view to determining what the effect on the navigation of this harbor may be; what we want is something to go on.

Col. Knight: If you can throw any light on the sedimentation process, and upon the quantity of solids to be removed, we would be very glad to get the light, on the sedimentation, on the removal of the grit——

Mr. Dean: My first question is in reference to the grit chamber.

Mr. Harrison questioned by Mr. Dean:

Q. Will you explain in detail the size of the grit chamber, in your plans, as you propose to build the sewers?

A. The size of the grit chamber will be sufficient, in the
140 opinion of the United States authorities to do the work or remove such an amount of grit as is necessary to prevent any obstruction to navigation, and we have so stated, sufficient to do the work, reserving to the United States government the determination of its sufficiency, and nothing done in the completion of our work will affect the navigation interests or the interests which the United States has, under the Constitution; and all will be done subject to the approval of the proper authorities of the port of New York; the plans will be submitted to them, as was stated in our application.

Q. As I understand it, the purpose of your petition before this present Board is to present your plans in detail, to show them how much solid matter will come out of the sewer, and go into the water?

A. You are very much mistaken as to what is the purport of our proposition; the object of our petition as is shown by the application,—we have proposed to put a structure in the soil of New Jersey, under the waters of New York and Newark bays and at certain points shafts, and so on; that structure will rest upon land of the state of New Jersey, and on land deeded by the State of New Jersey to the United States, in which New Jersey has the reversionary right——

Col. Ruffner: I object to this altogether. The Board likes to get information, but we are not here to settle points between one State and another. I think if the Board wishes to ask questions, if there are any doubtful questions, but if other gentlemen have doubts about it, this is not the place to settle them. I object. The Board
141 is not asking the questions.

Mr. Dean: May I present my side of the argument?

Col. Ruffner: You may make a statement of your own point of view, as much as you choose,—you can question, in your statement, the statements of other gentlemen, if you wish to, but I do not like to have you ask anybody else for further information.

The Chairman: Mr. Dean, will you please outline to the Board just exactly what it is you wish to accomplish by your questions?

Mr. Dean: I will say that the petition to this Board has been read, but I wish to draw attention to the fact that they request permission for the construction and permanent maintenance of tunnels under the navigable waters of Newark and New York bays, as shown by plans attached, before you. Then it goes on in five or six requests and asks permission to complete—to build a sewer.

Now, the amount of solid material that will come out of that sewer as effluent is very material for us to determine because if it is insignificant then New York can have no objection to the construction of that sewer, but if the solid matter is not properly removed in this screening chamber which they have described to us, that is if the size of the mesh of this screen be one-eighth of an inch mesh it will remove a certain percentage, and we ought to know this percentage, in order that we may be able to determine the result or the probable result of the screening they propose, as it has been determined in any of the different disposal plants where the sedi-
142 mentation system is used; it has also been determined definitely what percentage of solid matter there is in ordinary sewage. For instance, I would like to find out whether this sewer is going to—which is going to dispose of the sewage from these different municipalities, whether it will carry storm water, because storm water largely differs from ordinary sewage, in other words, there is not so much organic matter in sewage in what they call the combined system as there is in the separate system. Of course, in a separate system it takes away the storm water in one pipe and it takes away the sewage from houses and factories in another pipe, and I would like to know if they are going to use the combined or separate system, and as that determines largely the amount of solid matter in the sewage, then I say we can only determine the size of the solid matter, as it differs as explained under the combined or separate systems, by determining how much sediment is to be taken out in this grit chamber, and that, of course, consists of sand and broken up particles of soft organic and mineral matter, and then, when from certain storms they have, the sewage is permitted to run down at a certain rate of speed through the grit chamber, the tunnel is full, the question is, how much is going to be sedimented out, what certain proportion of the detritus can be settled out, and what certain proportion is going to escape? We would like to know how

much is going to be taken out in the settling basin, and by the screening.

The Chairman: Why do you want to know that?

143 Mr. Dean: My point is just this: I don't see how you gentlemen can pass upon such a plan as this unless you can say, or the experts can say, how much of the solid matter is to be withdrawn from this sewage, how much shoaling is going to be caused in the harbor, the amount of shoaling to be represented by that capacity, by the number of cubic yards of solid matter removed, the number of cubic yards of shoaling per year depends upon the amount of solid matter removed by screening in the screening chamber, in the grit chamber; the whole question, the most important point in this whole proposition, is to find out whether there will be shoaling; if there will be shoaling, then we earnestly contend that this permit should not be granted. If there is no shoaling the only question is whether these dispersion pipes, so called, will be placed at a sufficient depth in the water to permit of vessels passing by at low water.

The Chairman: According to the endorsement of the Chief of Engineers, the Board was directed to take up the question of having any deposited matter or shoaling removed by the people controlling the sewer——

Mr. Dean: Now, if it may please the Board, they have not shown what percentage they are going to remove of solid matters from this sewage——

Col. Knight: Why do you want to strengthen their case?

Mr. Dean: I want to find out——

Col. Knight: Don't you think the mere presentation of a

144 case without giving required details——

Mr. Dean: If they are willing to stand on the 1908 report of the Passaic Valley Sewerage Commission, then I am willing to say that——

Mr. Riker: Put that in your bill you have before the United States Supreme Court——

Mr. Dean: I wish to say that the suit which the State of New York has brought in the Supreme Court of the United States is in no way concerned in this hearing at all. He (referring to Mr. Riker) is now referring to that case. The legal questions will be taken up in that suit, but the reason for the opposing the granting of this petition at this hearing is for fear that your Board will grant a permit without having investigated every detail in this immense big subject, and which, if their permit was granted, would, to a certain extent jeopardize the case in the United States court, in which regard the Department of Justice is here represented by Mr. Miller, and to a larger extent where we are hoping within the next year to have further investigations made, and I might quote from different reports of different engineers, from one engineer especially, Mr. Allen Hazen, considered to be one of the best sanitary engineers in this country, where I believe he says that engineers are themselves *are* very doubtful as to what the effect will be in New York harbor, and it seems to me that the only way we can determine that properly

is to have the Department of the Interior make a complete and exhaustive study of the differences and conditions of the tides
145 in this harbor. I understand that the Metropolitan Sewerage Commission has done some work along those lines, but they have been limited to a certain extent in their investigations, and I think that this matter ought to be fully investigated.

We have had some general statements as to what the effects of the tides are. We learn, from the United States Government report of 1887, that there is an under-run, as stated from their own investigations—in the Government report—which goes up the Hudson river, but that was so many years ago that conditions might have changed, and we wish to investigate all points thoroughly. That is the reason why I wanted to bring these matters out fully. If you will permit me, I have sanitary experts here and I will be glad to have them make definite explanations of these matters for the purposes of this Board. We earnestly request that no permission be granted to these petitioners unless it is after a very exhaustive and full examination of this matter, and I do not believe, from my own stand-point,—the way I look at it, I do not consider that a full investigation can be made of the hearing of this application with what it involves, until these gentlemen can tell us how much solid matter they are going to remove, and that cannot be determined until they tell us the size of the screens, and how they propose to remove the detritus from the screening chamber, until they tell us the size of the grit chamber and how much solid matter such as sand and grit and mineral matter to the cubic yard they are going to get out.
146 They have failed to tell us anything at all—except by their silence—about the grease and soap that will work through the screen. They cannot hope to remove grease by their screens, and yet they say they are going to remove all of the floating material.

You know that in Boston harbor—and I am only making this statement in a general way,—we have experts here to prove it, if you wish to go into it—what the conditions are in this regard. We know that in the Summer time there are obnoxious odors which come off over the polluted area.

In the Government report of the investigation of the Boston sewage problem they state the exact existing conditions which have prevailed there at Boston, although they do not go into as much detail as we would if we went into this matter over here, but we do know that in Boston harbor the polluted area extends fully two and one half miles, and we know that these things exist, and we know that they cannot remove the grease through treatment by screening, and we do not know how they propose to do it. Now, if those conditions prevail at Boston where they have a tidal movement of fourteen feet—I am not positive as to this—in the polluted area, and with the tide movement in New York harbor of between four and six feet—I am not absolutely sure as to that point, and *the* it is an important point, I am going to ask Mr. Harrison these questions so as to bring out how much solid matter they are going to remove through their screens, what is the size of their grit chamber, and as to the effect of the sedimentation they propose?

147 (The following is read by direction of the Board):

"NEW YORK, November 30th, 1908.

D. W. Lockwood, Col., Corps of Engineers, United States Harbor Line Board, Army Building, New York.

GENTLEMEN: I shall not be able to attend the public hearing set for the morning of December 9th, notice of which you have been kind enough to send me.

I would respectfully make the suggestion, however, that whatever restrictions upon the discharge of sewage into *into* New York Harbor or its tributary waters may be finally determined upon, that they should be made equally applicable to communities in the State of New York and in the State of New Jersey. Any attempt at discrimination as regards privileges to be extended to each State can only result in delay and subsequent complications. The first requisite for a proper consideration of this subject is the certainty that the National Government so far as it is able to control the situation will treat each State fairly. If it shall appear that communities in New York State have already, acting in advance of New Jersey,—polluted the waters of the Harbor by the discharge of sewage then corrective measures should be sought for the facts as they exist.

I would respectfully submit that a sewage flow from the East into these waters is just as deleterious as a sewage flow from the West.

Yours truly,

(Signed) CALVIN TOMKINS."

148 "BOROUGH HALL, NEW BRIGHTON,
NEW YORK CITY, December 1, 1908.

Col. D. W. Lockwood, Corps of Engineers, Chairman Harbor Line Board, Army Building, New York.

SIR: The writer has been asked by the Staten Island Chamber of Commerce to be one of its representatives at the public hearing which you are to conduct on the morning of Wednesday, December 9th, in connection with an application of the Passaic Valley Sewerage Commission of New Jersey, for government consent to its constructing and maintaining a proposed great trunk sewer outlet in New York Harbor. He regrets that a prior engagement in Boston will prevent personal attendance, but instead will present the following notes.

During the three years of its existence, the writer was a member and officer of the New York York Bay Pollution Commission, the first official body to take up the question now before your honorable Board, and as Consulting Engineer and Commissioner of Public Works of the Borough of Richmond for the past seven years, has had under observation more or less constantly the conditions of the Harbor as to sewage pollution. In the design and construction of sewers for this portion of New York City under the President of the Borough, the question has been kept to the front and designs have been such as to provide for the future interception of sanitary sewage and the first discharge of storm flows, so that they may be
149 treated and the effluent rendered inoffensive, in-occuous and non-putrefactive.

Properly providing for the sewage of New York City and neighboring municipalities in both New York and New Jersey, is one of the great problems of the day. Much has been said about the shell fishery industry as a factor in the question at issue, and it is important; but aside from that, the comfort and it might be said the sentimental wishes of the inhabitants of New York and vicinity are of tremendous import.

The Harbor of New York and its tributary streams should be kept free from all refuse; floating, suspended or in solution. No community should be permitted to continue to an indefinite future the disposition therein of the solids of sewage wastes. Probably at the present time there is an average of twelve hundred to fifteen hundred tons of deposit daily. Some of it changes by putrefaction into gaseous form and passes off into the water or air, but the greater bulk of it remains as a filthy deposit on the bed of the Harbor, a little perhaps passing out to sea.

The large flow of fresh water coming down the rivers and the tidal inflow of more or less clear sea water, makes conditions safer than in some other of the great sea port cities of the world; but even New York and vicinity cannot long continue to abuse these advantages and not suffer seriously in consequence.

Now, to the point of immediate consideration, the application of the New Jersey Commission to your practically untreated sew-
150 age in large quantities into New York Bay at a specific point or several neighboring points. It may not be strict justice for New York City to continue to do itself what it wishes to forbid a neighbor from doing, but it is easily within the possibility of the New Jersey project to so care for and treat the sewage gathered from a number of localities, that the effluent, which could then be admitted to New York Harbor, shall be inoffensive in-aerious and nonputrescible, or practically so. We do not consider that it will ever be necessary for New York or the whole Metropolitan district to so treat its sewage as to make the effluent pure, but with the results accomplished as suggested, and readily possible, diffusion, marine organisms and chemical action of the sea water will effectually care for all that remains, so that the harbor will be kept pure and clean.

We therefore would protest against any consent being granted to the Passaic Valley Sewerage Commission, that is not coupled with the absolute provision that such sewage as may be permitted to enter the harbor shall meet the foregoing requirements.

Yours respectfully,

LOUIS L. TRIBUS."

Mr. Harrison questioned by Mr Dean:

Q. Mr. Harrison, I refer you to the special report of the Passaic Valley Sewerage Commissioners to the Governor of the State of New Jersey submitted June 8th 1903 and on page 13 read you the following which appears over your signature: "Experiment and
151 experience have shown that in the sewage of Eastern American cities these one hundred gallons per head will contain about one-one-thousandth part of organic matter and about the same

of inorganic or mineral matter, or about a little less than one pound of organic matter to each person per day."

A. That is according to Rathbone's measure, also the Royal English Society; it is less than George W. Fuller's investigation made in the last few years, but according to Roesler & Becker, on Sewage, that is about right; it is also in the investigation of the Massachusetts State Board of Health—that was about their figure.

Q. In other words, there is two parts per thousand of solid organic matter——

A. No, one part of organic and one part of mineral.

Q. Making two parts of solid matter altogether?

A. Two parts per thousand per person.

Q. Do you *subscribe* (agree) with Mr. Hering in a statement he made this morning that the sewage would consist of one part in five thousand?

Q. I did not hear Mr. Hering make the statement; besides, the sewage of Paterson is heavier than that; Orange is also heavier than that. I think that what he said must have been that it was no heavier than the average eastern American standard.

Q. I understood him to say that the sewage which would enter the grit chamber would have solid content of *one* (five) part in one thousand?

152 A. That may be his judgment.

Q. Engineers are not agreed on that?

A. Neither are lawyers; it is a question technical.

Q. What will be the amount of sewage, in gallons, which will be the ultimate capacity of the sewer?

A. The ultimate capacity of the sewer——

Mr. Riker: Does the Board want to go into that matter, it has been covered by the direct statement?

Col. Knight: That matter has been covered by direct statement this morning.

Mr. Dean: The reason I am asking the question is that I did not consider the statement they made this morning corresponded with the statement they made in their report. Their report says that the trunk sewer will have an ultimate maximum capacity of three hundred and sixty-five million gallons per day, and that the average daily sewage would be three-fourths of that amount; this morning they stated that it would be two-thirds of this amount, and if they are going to try and build——

Mr. Harrison (interrupting): Let me answer that question in regard to Mr. Hering. Mr. Hering gave you the amount of solids in the water which come right through the sewer; I have given you the average American sewerage, of one hundred gallons per head per day, that it would be made up of one part in one thousand of organic and one part in one thousand of mineral solids. The water that will go through this sewer will be two hundred gallons per head and sometimes three hundred gallons per head.

153 Mr. Dean: As I recollect it, the basis of calculation stated in your 1908 report was one hundred gallons per head——

Mr. Harrison: No; you are not correct. The house sewage was stated at 150 gallons per head, ground water leakage of the Passaic River, one hundred thousand gallons per square mile, East, and seven hundred thousand gallons per square mile; trade waste not exceeding ten per cent of the amount at the lowest. What the trade waste will be in 1940 is properly a calculation of averages.

Mr. Dean: Gentlemen, I can see we are going to have great difficulty in getting the information we require; will you please try and establish by the witness any definite statement given as to this plant?

Col. Knight: That is all before this Board; now, then, you differ with him on the question of the solid content; regarding these averages, and so on. Now, then, you have his statement, and you have the statement of Mr. Hering. If you have anything to gainsay it, why not bring it out by evidence? We are informed of that——

Mr. Dean: If they do not agree in certain material respects possibly we could make them agree by showing some other——

Col. Knight: I do not think this Board would care to have a forced agreement. We have these two statements giving the maximum and minimum of the solid material they can get out of the sewage and that will go into the water; if these things are wrong, why not
154 establish it by witnesses and give the Board the truth in the case, give the Board the true figures, bring out the facts of these proportions of solid matter. It may well be, as you can readily see, that if that proportion should be so small that distributed over an indefinite area it will not make a deposit of an inch in years, there is no interference with navigation, so that, how much you are going to remove is getting the cart before the horse, if there is not enough there to effect navigation, whether you remove one-tenth or one-quarter of it is immaterial.

Mr. Dean: Well, then, Mr. Harrison, do I understand that the statement you made about the average sewage of the average American citizen is applied to the sewage as it will come down this trunk sewer?

Mr. Harrison: It probably will; that is the statement which is accepted by engineers throughout the country and is about right; two parts to one thousand, the normal constitutents of American sewage.

Mr. Dean: Then I do not understand your answer to the question about the average number of gallons ultimate capacity.

Mr. Harrison: The average ultimate capacity we assumed would be for a population of one million five hundred thousand estimated to be reached in about 1940. We cannot keep out of that sewer a certain amount of the ground water, and we estimate that the ground waters are to come in and will practically add eighty per cent to that one hundred gallons a day for the population of one million five hundred thousand, their sewage, eighty per cent of the
155 ground waters that we cannot keep out, perhaps some factory waste and that will make an ultiamte average capacity for the sewer of two hundred and fifty million gallons for which we provide a sewer which will carry about three hundred and sixty million gallons because from four o'clock in the afternoon—in the morning, until four o'clock in the night perhaps, the sewer will run

a maximum which will be double the minimum at four o'clock in the morning but the sewer has got to be big enough to carry the maximum, the peak of the flow.

Mr. Dean: Do I understand that the Commission has not adopted any definite plans as to the grit and screening chamber?

Col. Knight: I do not think the questions are material. It is not necessary to go into that; whether they have adopted those plans or not, we do not care; that is already before this Board.

Mr. Dean: Mr. Harrison, has this commission investigated fully all of the alternatives which may be adopted?

Col. Knight: I object. It is not the question before the Board, how many alternative they may have studied; the question is whether the permit be granted to this Commission for this sewer as affecting navigation.

Mr. Dean: Will you tell us, Mr. Harrison, the depth of the height of the sewer of the top of the sewer below New York Bay where you propose to erect the shafthouse?

Mr. Harrison: At Robbins Reef?

156 Mr. Dean: Yes.

Mr. Harrison: Below New York Bay?

Col. Knight: We have got the profile of this proposed shaft-house; that is on record here; that is established by the application.

Mr. Harrison: The statement made in our application is that the bottom of the shaft will be forty feet below high water reserving the right to go lower.

Mr. Dean: Mr. Harrison, the plan you have submitted, is that the final plan for the construction of the sewer under New York Bay?

Mr. Harrison: I guess not; we will probably spend one hundred thousand dollars or so before we get the plan final.

Mr. Dean: Then you would not state that the sewer will be so many feet below high water, or will be so many feet below mean low water?

Mr. Harrison: Yes; we have; it will be at least fifty feet; maybe sixty or seventy—the State of New York is not interested in that; it will be in the lands of the State of New Jersey——

Col. Knight: He has given a minimum there, reserving the right for a maximum. There are two conditions there——

Mr. Harrison: Those conditions are apparent on a rainy day—those are only minimum conditions; there will be a maximum of that.

Mr. Dean: Coming back to the storm water, just how much
157 of the storm water is to be taken through this sewer?

Mr. Harrison: In general, part of this Passaic Valley Sewerage District territory now has a separate system and another part has a double system; it is the purpose that the whole territory shall be equipped with a separate system; the only proportion of storm water we will get into the sewer when it is first completed will be the first rush of storm water; then it is proposed to cut this off by automatic pipes and put it into the river, and when we shall have reached that point in the working of this sewer, the community shall put in a separate system very soon; the law provides that the

apportionment for maintenance is to be based upon the proportions of water delivered from each of the communities, so that it will be to the interest of every community to put in a separate system and keep the amount of the sewage down, because otherwise the smaller communities would have to put as much where they have the double system or combined system as the larger cities would, having the separate system——

Mr. Riker: Does the Board feel that this is a matter for them to consider?

Col. Knight: The Board is allowing that answer to go on the record——

Mr. Riker: I thought that I would have an opportunity to object——

Col. Knight: The Board is merely trying to get information. The Board has its object. The Board, I think, will stop whenever they think it improper, as I think it has shown a disposition to do.

158

Mr. Dean: I really wanted to bring out the amount of solid contents which goes into the sewer from the storm water. From the statements which have been made it is impossible to ascertain just how much solid matter there will be in the sewage as proposed to be discharged. I have here Professor Landreth and Dr. Jackson, who tomorrow morning will make a statement here and also give testimony especially with reference to the effect of the sewage on the harbor of Boston, which is particularly relevant because of the expressed purpose of the Commission to adopt in a modified, and improved, form, the system there used.

Col. Knight: You will be prepared to show that the sewage in Boston harbor is treated substantially as they propose to treat it by this plan? In other words, if you are not so prepared to do, your statement as to Boston Harbor won't have any bearing——

Mr. Dean: That comes right back to the capacity of the grit and screen chamber; the only thing I can do is to suppose there is a similar or equivalent treatment——

Col. Knight: You will be prepared, when you make the comparison,—you will be prepared to explain the Boston method in detail?

Mr. Dean: Yes, sir.

The Chairman: It is now a quarter of four, and the Board will stand adjourned until ten o'clock tomorrow morning, December 10th, when it will hear anything further that may have to be offered on this subject.

159

Second Day.

December 10th, 1908—10 a. m.

The Chairman: Gentlemen, if you will come to order, the meeting will open.

A letter was received this morning by the Board: I will read this letter as it came to the Board:

"NEW YORK, December 9, 1908.

New York Harbor Line Board, 39 Whitehall Street, City.

GENTLEMEN: Having attended this morning at the hearing on the subject of the Passaic Valley Sewer, and understanding that you will not be able to hear arguments from individual associations, we respectfully ask you to note our appearance on behalf of the Sea Gate Association and of the Atlantic Yacht Club, both at Norton's Point, in opposition to the plan of constructing a sewer, as described this morning by the engineers of the Commission.

From our observation of the water, especially in Gravesend Bay, we are convinced that, if any change is made in the handling of sewage, it should be a radical one, and on the lines described by the Commission's own engineers this morning, as existing in Berlin and Paris. We are of the opinion that, if Newark wishes to change its method of disposing of its sewage, absolutely no sewage from that city and the adjoining cities should be in any manner discharged into New York Bay.

We are yours very respectfully,

BARTOW S. WEEKS,
Attorney at Law, Representing the Atlantic Yacht Club, 2 Rector Street, N. Y. City.
GHERARDI DAVIS,
Attorney at Law, Representing the Sea Gate Association, 44 Pine Street, N. Y. City."

The Chairman: The first part of this letter was evidently inspired by a misunderstanding of the situation. I do not recall that anything occurred yesterday that indicated a desire on the part of the Board not to hear any one who had anything to offer on the subject. The gentlemen were communicated with by telephone this morning and the misunderstanding is corrected. They were convinced that they were wrong in the statement they make in the commencement of the letter; they also requested that the letter be read and form a part of the record, which will be done.

The next letter is dated:

"WASHINGTON, D. C., Dec. 8, 1908.

Captain Parsons, 6 Coenties Slip, N. Y.

DEAR CAPTAIN PARSONS: I regret it will be impossible for me to be in New York at Harbor hearing tomorrow. I have written Mr. H. C. Hunter (Sec. N. Y. Dry Dock Ass'n) 30 Church Street, Tel. 458 Courtlandt, to consult with you.

Unless dumping of sewage into New York harbor is restricted the harbor will ultimately be on a large scale what Gowanus Canal and bay are now in a smaller way, an insult to decency and a bar to sanitary and business progress. The City is now spending over a million dollars installing and hereafter will spend annually a large sum maintaining and operating a plant to clean Gowanus Canal and Bay. If New York harbor is allowed to get into similar condition I doubt whether tens of millions would

cure the evil. It will be infinitely better and cheaper to prevent than cure it.

Our Company, the "Yebo Yacht Basin Co." have a large and valuable water front plant at foot of 23d Street Brooklyn, during the past ten years the income therefrom has decreased one half as a result of dumping in and pollution of Gowanus Canal. The sewer refuse settles on the bottom and a gas arises that destroys painted surfaces so rapidly that in hot weather yachts cannot stop an hour in the neighborhood without danger to their decorations and men cannot sleep on board vessels without danger to their health.

The condition at Gowanus has retarded business development for years and caused enormous loss to the property owners in the neighborhood.

Yours truly,

WALLACE DOWNEY."

The Chairman: The following has also been submitted:

"NEW YORK CITY, December 10, 1908.

New York Harbor Line Board, 39 Whitehall Street, New York City.

GENTLEMEN: In order to save the time of this Board dur-
162 ing the conduct of this hearing on the Passaic Valley Sewer, I beg to submit in written form the protest of our City Improvement Society against this proposed sewer. While we realize that this question will be decided chiefly on engineering and scientific grounds, we feel that as a civic organization we should at least register one more protest against what must prove to be a serious invasion of the rights of the citizens of New York City to the enjoyment of life and the pursuit of happiness.

Respectfully yours,

CITY IMPROVEMENT SOCIETY."

The Chairman: The Board is now prepared to hear anything further on this subject that those present may care to offer.

Mr. Dean: Mr. Chairman and Gentlemen, we would like to ask Dr. Jackson if he objects to stating the conditions in Boston Harbor as he knows them as a comparison with the conditions in New York Harbor.

Dr. Jackson: I have been connected, as chemist and sanitary expert, with the New York Bay Pollution Commission, and the Metropolitan Sewerage Commission of New York, and am director of laboratories of the Department of Water Supply of that district; I am also a member of the Pollution Committee of the Merchants' Association.

The similarity between the conditions in Boston harbor and those in New York harbor have been pointed out, but I wish to bring out some very essential points of difference between the Boston
163 harbor conditions and those in New York.

The sewage of Boston harbor is screened, passed through four large settling tanks, through and under a large settling tunnel, in all of which places considerable sediment is removed. It is

then allowed to flow out at some depth to beyond Moon Island, and as it flows out, it is deposited only one hour after the ebb of the tide; in other words, they are very careful not to allow the sewage to flow during all periods, as it has been found that it would flow back into Boston harbor and cause serious detriment there.

The Chairman: What sewer is that?

Dr. Jackson: The Moon Island sewers in Boston. The sewage of the Boston sewers——

The Chairman: Is that the one that enters in just below Deer Island?

Dr. Jackson: No; the Deer Island and Nut Island are smaller sewers and of more recent construction. I am speaking of the main Boston construction, which is that of Moon Island, in the outer harbor.

Now, it was supposed that when the sewage was discharged there, it would become intimately mixed in the waters of Boston harbor. As a matter of fact, as it discharges below the surface, it immediately boils up and spreads out over the surface, and that is because of the difference in the specific gravity of the sewage due to a difference—some ten or twenty degrees, in temperature and due to the difference in weight between fresh and salt water, which immediately brings that sewage to the surface just as if it was in a funnel, and
164 if discharged at a lower point the diffusion is very slight causing it to float out over the surface.

The last time I was at Moon Island, and I went there particularly to see the beginning of the discharge and to watch it during the entire period, and I know that there was practically no diffusion. Of course, the discharge there was not so deep as it is intended here, but the point is that the discharge there—from different points—it was put below the surface, and it immediately rises up, boils up from six inches to a foot and spreads out over the territory there for several square miles, in fact over the distance of the water, that is, as far as you can see, all the way over to what is called Long Island.

Now, all the examinations that have been made of that water show that the sewage is all practically within six inches to a foot of the surface; in other words, it does not intimately mix up with the salt water, and on account of those conditions—the difference in specific gravity, and coming to the surface as it does, it is spread out on account of that same difference in the water—fresh and salt. Then, of course, after spreading out over this broad territory, it becomes more or less quiescent, and then deposition takes place.

Now there is another essential difference in Boston harbor as the rise of the tide there is from twelve to fourteen feet at that point whereas in New York harbor it is from four to six feet only and that makes a very marked difference in the velocity which
165 would carry away these materials or depositions. The fact that the sewage here in this application, in New York harbor is to be deposited forty feet below the surface is not a very essential feature to my mind. I believe that that sewage, the moment it leaves the outfall, will rise suddenly to the surface, with considerable velocity, due to the quantity and due to the difference in the

rate of flow here and will, during the ebb tide, flow all the way between Robbins Reef, out through the Narrows and cause a disagreeable odor and unsightly appearance over that territory and during the flood tide will undoubtedly flow up around on both sides of Manhattan Island. There is no reason why this should not take place. The sewage which is deposited in the New York bay at the present time does exactly this same thing in a smaller way—on a smaller scale, for the reason that it is deposited in small outlets all the way 'round Manhattan Island, all the way around Brooklyn over a territory with a water line of perhaps thirty miles, and yet even with that distribution the sewage in New York harbor is practically all at the surface, all of the recent sewage and a chemical examination, and a bacteriological experiment and experiments which have been made and I have made most of them myself, show that this sewage is at the surface—all of the recent sewage—is at the surface of the water and down only a very slight distance is a very marked addition in the purity of the water—a marked difference in its purity.

Now, the first point is that the sewage will be spread out
166 over a very broad area of the harbor.

The next point is that the materials in suspension will be gradually deposited at points where the velocity has been slowed up.

The Merchants' Association feel that there is no valid reason why the sewage of the Passaic Valley should not be purified before it enters the waters of New York harbor.

Col. Knight: One or two questions, please:

Col. Roessler: I would like to ask this question: You refer to the rising of the sewage in Boston harbor due to the difference in temperature; is it not true that the temperature of the water in Boston harbor is quite a bit lower than the temperature of the water in New York harbor, and that therefore the difference between the temperature of the sewage and the water in which it is placed in Boston harbor is greater than the norm would be with reference to the Passaic Valley sewage and the waters of New York harbor?

Dr. Jackson: I did not say that there will be no difference—I do not get your point——

Col. Roessler: The temperature of the water is much lower up there——

Dr. Jackson: It is much lower there——

Col. Roessler: The temperature of the water up there is much lower than the temperature of the water in New York harbor is it not?

Dr. Jackson: Yes. In Boston harbor I was informed that the temperature which had been taken, the difference in temper-
167 ature between the sewage and the water was about twenty degrees; I am not sure of those figures, but that is what I was told there. I understand that the difference here in New York harbor would be between ten and twenty degrees.

Col. Roessler: Is that in Summer? That difference of twenty degre-s between the temperatures of the sewage and the water in Bos-

ton harbor, you know that the water up there is considerably colder than it is here.

Dr. Jackson: That is a sort of average. My statement was that it is about ten to twenty degrees here.

Col. Roessler: In New York harbor?

Dr. Jackson: Yes, sir; I think it is a fair statement, from my experience.

Col. Knight: You referred to the velocity of the flow of the tide at the sewer outlet being greater in Boston harbor than it is in New York harbor; do you know actually what that velocity of flow is?

Dr. Jackson: No, sir; I only know that the difference in the tides is very considerable and naturally the velocity of the flow must be greater. I do not know the actual velocity.

There was one essential point I would like to bring out, which I forgot. In the Summer time, in New York harbor—in Boston harbor, I mean, there is a deposit of from two to eight feet of sewage sludge between Moon Island and Long Island. Every Summer. This sludge backs up on the right of the Boston harbor and on the right of the outlet so that there are considerable flats exposed,
168 of sewage sludge, during the Summer time. The engineer who put the water pipe from Moon Island to supply the water for Long Island had to cut through this sludge to get his pipe through and he cut through from two to eight feet of mud, sewage mud which he assured me had certainly the essential odor of sewage mud at that point, from two to eight feet depending on the contour, of course, eight feet in the deeper portions, as the sludge settles into those parts.

Now, the reason that there is not a very heavy deposit in Boston harbor is because, during the Winter time this sludge, which is deposited in large amounts over several miles of territory is broken up by the very heavy sea at that point during the Winter and is redistributed, so that it is not apparent there. Much of it naturally goes out to sea; some of it is distributed over the near portion of the harbor; at all events, if it were not for the Winter storms which create a very heavy and high seas which they have at that point the sludge there now would be much above the present surface of the water at high tide.

And I want to point out a strange thing, and it is that the conditions which occur in the Boston harbor during the Summer time, are the same conditions which occur in New York harbor throughout the year, and that that deposition which takes place in Boston during the Summer time, of this sewage sludge, is going to take place constantly in New York harbor, instead of intermittently as in Boston harbor.

The Chairman: You mean to say that New York would
169 not get the benefit of the very heavy Winter storms they get in Boston harbor and which serve to disperse this deposit as you have stated?

Dr. Jackson: In New York harbor they have a double protection against heavy storms; they have the outer bay and the quiet waters of the harbor, which are unusually quiet for a harbor.

Col. Knight: How far from the mouth of this sewer is the effect of that Boston sewage noted; how many miles from the mouth of the sewer, where it is discharged into the Bay?

Dr. Jackson: There is no appparent effect — inches from the mouth of the discharge sewer, which it has been in any way able to measure; there are certain deposits at varying distances—fully a half mile inland towards Boston.

Col. Knight: Well, how far will the tidal currents carry that sewage?

Dr. Jackson: When the sewage is discharged, there is a sharp line on the North of the discharge, this is apparent and defined, and from the temperature of the water which indicates where the sewage is.

Col. Knight: How far does the tidal current carry the sewage so discharged?

Dr. Jackson: It does not flow beyond that point only a matter of a few hundred feet.

Col. Knight: A few hundred feet?

Dr. Jackson: That sharp line, which you can see extending off for a couple of miles shows the battle between the sewage,
170 which would flow towards the harbor, and the very strong current which occurs during the time of the outfall, at the other edge of the outfall.

Col. Knight: But that discharge is made on the ebb?

Dr. Jackson: Always, and one hour after the beginning of it.

Col. Knight: Well, then, the following flood then does not carry it beyond this line of demarcation you have spoken of?

Dr. Jackson: That is a matter which is very difficult to judge.

Col. Knight: But you say this line is apparent and sharply defined, and I asked you how far the tidal current carried——

Dr. Jackson (interrupting): This line is surface water——

Col. Knight: The line you speak of is on the surface of the water and you are speaking of the mass of material coming at once to the surface of the water, so we are treating of what is floating on the surface; you find the line of demarcation about a half mile inland; do you ever find it further inland?

Dr. Jackson: No.

Col. Knight: Then the recurring current of the tide does not work this sewage up into Boston harbor?

Dr. Jackson: I spoke of the deposit——

171 Col. Knight: I am speaking of the surface indication——

Dr. Jackson: That I am not familiar with——

Col. Ruffner: How many hours did you watch this?

Dr. Jackson: About two hours.

Col. Ruffner: About the time of discharge?

Dr. Jackson: Yes,—just before the discharge until the end of it and kept track of the facts; of course, there is a discharge of two hours, starting one hour after the ebb tide stars.

Col. Knight: Well, then, how do you reach your conclusion, as you have stated it, that if this flood does not move this material inland in Boston harbor so far as the surface indications are concerned,

that the flood tide will move it from Robbins Reef up around on both sides of New York harbor?

Dr. Jackson: As I understand this proposition, that discharge is not on the ebb tide, but during the entire period, and, of course, the conditions under those circumstances would be utterly different; that is, during the flood tide, the disagreeable part of the material, and the odoriferous part of the material would be carried up the harbor and around the City, and, during the ebb tide, would be carried out of the harbor.

Col. Knight: But, from the Boston statement, I infer, then, that if it all goes out of the harbor on the ebb tide, as you say, the recurring flood tide does not bring it back.

Dr. Jackson: I think not to any great extent—I think that
172 is account- for by the fact that it is practically open sea there—And the islands——

Col. Knight: Then this material, down here, discharged on the current of the flood tide, could not go farther inland than one flood would bring it?

Dr. Jackson: No; I think not.

Col. Knight: How far—Do you know anything about the tidal velocity here on the flood tide?

Dr. Jackson: I have not been personally connected with that work—I know of it through other sources—I know that the floats charted by the Metropolitan Sewerage Commission would easily go beyond the City——

Col. Knight: What velocity do you get from that?

Dr. Jackson: That I am not familiar with; I do not know the velocity; I know the condition that the floats put in at Robbins Reef will go up just beyond the Narrows if put in at the beginning of the ebb——

Col. Knight: Will the recurring flood tide bring that back as far as Robbins Reef?

Dr. Jackson: Most of them were deposited on the North shore of the island——

Col. Knight: I know, but those that were not deposited on the North shore, of course, would they come back as far as Robbins Reef?

Dr. Jackson: Of course, they meet the Hudson River effect: there would be an oscillation in the harbor and always would ultimately pass out further——

173 Col. Knight: In other words, then, the material could not possibly go farther North—could not go upstream farther than one flood tide would bring it?

Dr. Jackson: No; of course there is a difference in high floods——

Col. Knight: I am speaking of the average conditions?

Dr. Jackson: That would be the case.

Col. Knight: Then how far is Robbins Reef below the Battery?

Dr. Jackson: I do not know the exact distance.

Col. Knight: Then, if you do not know the exact distance, and do not know the rate of flow of the current, how can you predicate that this stuff will come up here on both sides of New York?

Dr. Jackson: For the reason that the floats put in at the Battery will go down beyond Robbins Reef and back——

Col. Knight: But would they come back as far as they went down?

Dr. Jackson: Nearly as far.

Col. Knight: Well, then, you still do not say how you reach your conclusion,—if you do not know the rate of flow, the velocity, or the distance, I do not know how you can assert that that material will go that far——

Dr. Jackson: Well, the material being on the surface of the water will very likely go about the same distance as the floats will go, and while the velocity of these currents in New York harbor have
174 not been very well worked out, it is fair to assume that where the floats will go the surface material will go.

Col. Knight: But you do not know where the floats will go. You only say that some put in off Robbins Reef go down to the Narrows and come back nearly as far or pretty nearly as far, but you do not know anything about floats from Robbins Reef coming up on both sides and around the City of New York——

Dr. Jackson: I think that is a matter that Professor Landreth, who follows me, may be able to answer.

Col. Knight: I simply want to get a foundation for your remarks that this material will be carried up on both sides of New York, on the Hudson river side and in the East River on that side of the City——

Dr. Jackson: The matter of the velocities of tides and those matters are not in my province.

Col. Knight: Then your statement about the material coming up on both sides of the City is not based on actual knowledge?

Dr. Jackson: It is based on what has been done in connection with the pollution of the harbor by the New York Bay Pollution Commission and by the Metropolitan Sewerage Commission, and upon the results of the float work as seen and as charted by those bodies?

Col. Knight: But the report—You have seen the special report of the Passaic Valley Sewerage Commission?

Dr. Jackson: I am not familiar with it.

175 Col. Knight: Then you are not familiar with all its statements concerning the tides and the floats in that report?

Dr. Jackson: No, sir.

Col. Ruffner: I understand you were appearing as an expert on these matters?

Dr. Jackson: I am a sanitary expert and an expert on sanitary chemistry.

Col. Ruffner: You are an expert merely on the chemical side of the question?

Dr. Jackson: General sanitation.

Col. Ruffner: Then your assertions as to where this material is likely to go is not expert testimony?

Dr. Jackson: I draw my conclusions, my inferences from what I have seen——

Col. Ruffner: Just what you have seen of these charts of the lots?

Dr. Jackson: I have spent probably as much time on New York harbor, studying these matters as any other one man; I have collected the matters of research in pamphlets and they have been sent around to the various interests and engineers——

Col. Ruffner: You are not an expert on the flow of the tides and tidal action?

Dr. Jackson: Not on the flow of the tides.

Col. Knight: Now, then, that takes out your statement that this material would come up around on both sides of New York
176 City. Now, then, you stated that this material when discharged from these pipes will rise at once to the surface, that because of the different density, specific gravity and temperature will bring it suddenly to the surface and that it will hang there and not be readily diffused——

Dr. Jackson: There should be some diffusion, of course,—there is same in Boston harbor——

Col. Knight: That is, by diffusion, you say; but by specific gravity, you say the effluent rises as a rule to the surface,—then how do you get the deposit in the bottom of the channel in the lower bay here?

Dr. Jackson: That is from different, heavy, material.

Col. Knight: But we have no heavy material,—you have described the amount of sedimentation—you have said that it goes through several settling tanks and through a long tunnel, and that then, as a result of lesser specific gravity, it rises at once to the surface; then where is the material going to come from that is going to fill up and diminish the navigable portion of the harbor?

Dr. Jackson: It is eventually deposited. As the result of the temperature, the suspended matter rises on being discharged, at once to the surface, and floats out over the surface, and then slowly deposits.

Col. Knight: What causes it to acquire the extra specific gravity, then, to drop it to the bottom of the bay?

Dr. Jackson: There is an action of salt water on sewage material which is productive of the condition which, I think Dr.
177 Soper brought out yesterday,—there is a precipitating action on the material, the suspended matter in solution——

Col. Knight: What was brought out yesterday was a photograph showing vials of different colors,—but no determination as to the amount of sedimentation——

Dr. Jackson: And we know that in salt water the sedimentation is greater than in fresh water, and a great many experiments have been made to show that——

Col. Knight: But now, what proportion, say, of a cubic foot of sewage comes out and is kept afloat by this specific gravity that you referred to as being true out at Boston, what portion of a cubic foot of sewage, or of the heavy constituents of sewage thus in suspension as you have stated, just what part of that will ultimately be made

heavier than it was when it came out of the sewer so as to form the deposit——

Dr. Jackson: You mean the matter in suspension?

Col. Knight: This matter that changes somewhere by contact with sea water, changes its specific gravity and drops?

Dr. Jackson: The sewage precipitates in time, it changes its specific gravity in solution and is then deposited. It is, as you might say, when the matter is surrendered, the residual deposit, which is determined by the salt in the water.

Col. Knight: Have you ever determined the parts in a thousand that that heavy matter that is deposited or precip-
178 itated form; have you ever determined how many parts in a thousand of ordinary sewage?

Dr. Jackson: That, of course, differs very widely with different sewages.

Col. Knight: Have you determined it for any of them?

Dr. Jackson: The chief pollution in suspension would naturally precipitate in course of time—only a question of time.

Col. Knight: Specify it; its volume; does it vary? Can you tell me between what limits it varies? Don't you see, the important feature is, here, if there is going to be an interference with navigation due to shoaling of the waters due to deposits, it is important to establish the rate of that deposit. Now, if you can give anything definite bearing on that, it is important to present it. You appear now without any special information as to the tides or currents, but you do appear here as a chemist: Now, can you tell us, from any analysis or from your observations of any sewage, how much sewage, solid matter, in parts to the thousand, will be discharged after this process that you spoke of, at Boston, has been completed?

Dr. Jackson: I should say, anywhere from two hundred to one thousand parts in a million; that is, one thousand parts in a million would be one part in a thousand.

Col. Knight: That is based upon your own knowledge?
179 Dr. Jackson: That is a general statement, based upon examinations of a great many sewages.

Col. Knight: Based upon your own examination?

Dr. Jackson: Yes, sir. I have had a great many years' experience and have made a very considerable study of the sewages of different cities——

Col. Knight: We are not asking that. From the fact of your appearing here as a witness on behalf of the opponents of this application, we take it for granted that you are present as an expert. Now, as the result of your own work, can you tell us anything as to that proportion? You say, from two hundred to one thousand parts in a million: Is that based on actual examination you have made?

Dr. Jackson: It is based on actual examinations I have made at Boston. The one part in a thousand is probably the amount that would occur at this point.

Col. Knight: You can say then, that from two hundred to one thousand parts in a million will be discharged, or may be expected to be discharged in Boston by this system after all of this process is

completed, or is this the part you find in sewage before it is subjected to any treatment whatever?

Dr. Jackson: That is the proportion I find in the sewage before treatment.

Col. Knight: Now, how much of this is removed by screening and sedimentation in the Boston treatment?

Dr. Jackson: In the Boston treatment, it is somewhere about one-half that is removed. But those figures of two hundred parts to the million will not apply to Boston.

180 Col. Knight: Well, we will take one in a thousand as the base. You say you think one-half of that is removed? Have you any means of determining—have you any measure—or have you ever measured it? Or, have you determined it by the amount of material you find in deposit in the plant as a result of the process of purification?

Dr. Jackson: I was assuming those figures from the analyses of the difference between the two; between that which goes over to Moon Island and that which flows out,—that which goes to the pumps.

Col. Knight: Then you have analyzed this discharge?

Dr. Jackson: I have not analyzed it myself.

Col. Knight: But you know——

Dr. Jackson: I have seen analyses, and I have also taken samples which I have been examining recently. The difference in that sewage over in Boston harbor as between ordinary sewages is very considerable. I would not think that that sewage would be a representative one or that it would represent what we would get here, for the reason that my examinations there of the compressibility of that sewage, which I have been making recently, have had very surprising results,—I have found that the compressibility there is as one to ten, that is, it requires the addition of ten parts of dilution to one part of sewage to prevent a disagreeable odor, whereas in ordinary sewages it will run as high as one to twenty or even one to thirty, so that that sewage is hardly representative of this.

181 Col. Knight: But, in fact, it is important. That brings us down to five hundred parts out of a million,—five hundred parts of material that can be positively deposited after discharge, out of a million that go to the works. That is, you remove one-half of one thousand, which leaves five hundred parts to the million to be discharged.

Dr. Jackson: In Boston——

Col. Knight: In Boston,—I am still speaking about Boston—what is the allowance of sewage per capita; of what does that sewage consist before treated; is it a separate system, or not?

Dr. Jackson: It is separate there for Moon Island, yes, sir——

Col. Knight: But does it take the sewage,—does it take all the sewage from Boston, or if, in Boston, the storm sewage separated from this? I want to know what goes into this plant?

Dr. Jackson: The Metropolitan Sewerage——

Col. Knight: Now you said—I am talking about the Moon Island sewer,—is that a separate system?

Dr. Jackson: Yes, sir; it is a separate system.

Col. Knight: In other words, nothing goes into that sewer, but the ordinary house sewage and factory waste?

Dr. Jackson: The ordinary sewage and waste; most of the storm water is cut out.

Col. Knight: What is the allowance,—the amount of sewage per head in Boston?

Dr. Jackson: I think about one hundred gallons.

182 Col. Knight: One hundred gallons?

Dr. Jackson: I think it is one hundred gallons per day.

Col. Knight: Then this is practically the same—or, is there any trade waste in that?

Dr. Jackson: I should assume there would be some.

Col. Knight: Do you think it is practically the same amount per head as is considered there in the Passaic Valley proposition?

Dr. Jackson: Yes. The difference in what is deposited, however, there would be a difference,—the large settling tanks and in the long tunnel in which they also settle out their material and remove it before they deposit it into the harbor.

Col. Knight: You said, remove it from that long tunnel; is that done?

Dr. Jackson: I understand it is shut down—shut off and the material is taken out occasionally.

Col. Knight: Taken out, how?

Dr. Jackson: Either pumped or shoveled out.

Col. Knight: Then it must be agitated, or mixed up?

Dr. Jackson: I think so.

Col. Knight: It would be best to do that on this tunnel here, would it not?

Dr. Jackson: It would be best to make such an arrangement.

183 Col. Knight: Now, another matter, with respect to that sewage coming up on both sides of New York harbor, you know nothing about the preponderance of the ebb discharge of the East River over the flood?

Dr. Jackson: During the flood tide the Hudson River flows down into the sea, and then flows out again.

Col. Knight: How about the East River?

Dr. Jackson: The East River flows eastwardly during that time.

Col. Knight: During the flood?

Dr. Jackson: Yes.

Col. Knight: Well, now then, during the ebb the East River goes down this (indicating) way; does it run about the same quantity as the Hudson river? Are the quantities—the contents of the tide in the rivers equal?

Dr. Jackson: Probably not; I do not know that that has ever been determined.

Col. Knight: Oh, yes; it has decidedly been determined. There are four hundred million cubic feet preponderance from the East River on the ebb tide over the Hudson river: Have you any condition like that in Boston?

Dr. Jackson: The conditions in Boston are that there are a number of small islands out above this point.

Col. Knight: I know, but have you anything like that tidal discharge, any single preponderant of four hundred million cubic feet? Have you anything corresponding to that as a method of dilution in Boston?

184 Dr. Jackson: I do not think there is any great difference between the discharge through the East River and the discharge through these various islands in different directions in Boston harbor; the action of the tide is about the same.

Col. Knight: I think the hydrographic conditions are entirely different there.

Do you know anything about—since you say you have been studying this sewage here—do you know anything about the sewage down at Gowanus Canal? And Newtown Creek?

Dr. Jackson: I do; I have made a great many examinations of it.

Col. Knight: Well, how would you compare the condition of the sewage at the head of that Creek and at the mouth of it?

Dr. Jackson: At the head of Gowanus Canal it is a very strong quality of sewage——

Col. Knight: Yes?

Dr. Jackson: As it goes further down it is diluted by factory waste; there is a great deal of precipitation from those wastes, and at the outlet it is somewhat more diluted than the ordinary sewage, but much worse at the surface than below—through the Oak Run——

Col. Knight: How would it compare at the mouth with the Boston sewage,—just at the mouth,—not at the top of the Canal,—but the sewage after it is treated by those works, but as it goes into those works?

185 Dr. Jackson: In appearance, it is very much darker—the comparison is not a very good one for the reason that we have factory waste there, which has a precipitating action in the Canal itself, and the conditions are entirely different, but a comparison——

Col. Knight: Well, you have the standards by which you compare sewage—whether sewage is harmless or not,—you have the comparisons to determine the degree of contamination in the water, haven't you?

Dr. Jackson: Yes; I should say that our chief comparative requirements are provided for, and the prospect of precipitation, the amount of water necessary add to that sewage to keep it from giving off a strong odor on incubation.

Col. Knight: The amount of water to keep it from giving off a strong odor,—then, taking that sewage at Boston, do you know what amount of water would keep that from being offensive?

Dr. Jackson: About one to ten, I should say, or less.

Col. Knight: Then, you would want to dilute it about one to ten?

Dr. Jackson: Yes. Ordinary sewage is diluted about one to twenty.

Col. Knight: Ordinary sewage? This Boston sewage is only half, as compared with ordinary sewage? Boston sewage is only half as strong, do you mean to say?

Dr. Jackson: That particular sewage is weaker in precipitates.

186 Col. Knight: This sewage which comes out of the Boston sewer, treated at Moon Island, you rate that as only half as strong as the ordinary sewage?

Dr. Jackson: Yes. I do not know that—Yes, I think I can safely say that. I have made precipitation tests on it which gave that result, in many tests, too.

Col. Knight: Has any test been made of that water at Gowanus?

Dr. Jackson: Yes; the proportion is as one to thirty there; it is stronger there.

Col. Knight: One to thirty at the mouth or the head?

Dr. Jackson: At the middle of it. I should say one to twenty at the mouth.

Col. Knight: Then, taking it as one to thirty, what do you mean by that, in ordinary English?

Dr. Jackson: The amount of material which is there, would have a decomposing action, would be strong enough, if thirty parts of water is added to it, and it is allowed to settle, and it is allowed to stand with the sediment in it, it will develop a strong odor, and lose all of its oxygen, all of the air which is in solution,—that is the test of the organic strength of it.

Col. Knight: Then, it is still harmful after that dilution of thirty to one?

Dr. Jackson: At that point it will just putresce, beyond that point it will not.

Col. Knight: Then thirty-one to one would make it safe,

187 and remove the offensive character?

Dr. Jackson: I do not know as to safe; but it would remove the offensive character.

Col. Knight: Well, then, eleven to one would remove the offensive character at Boston?

Dr. Jackson: It would, if diluted with the water, but if it is floating out over the surface, it does not have the same effect. We know very well that the offensive character is not removed on the surface of Boston harbor, for the reason that you can smell it, a very strong stench, over a very wide area: That is just the point; that it is not diluted.

Col. Knight: Well, what measures have been taken down at Gowanus creek or Gowanus channel to clarify or purify that?

Dr. Jackson: We are installing a pumping station to flush out the channel.

Col. Knight: What is the discharge of the creek?

Dr. Jackson: Those figures,—the amount of the discharge, are not within my province.

Col. Knight: You do not know, then, of any relation between the

discharge of the creek and the capacity of the discharge pumps in the pumping station?

Dr. Jackson: No.

Col. Knight: You do not know the proportion of water that is to be furnished to dilute that?

Dr. Jackson: No, sir: The action is one of flushing, as I understand it. They are to remove all the material, I understand, flush it out into the harbor.

Just one other point, if I may: You spoke of that strong discharge of the East River, into New York Harbor. That is true, in volume, but it does not have the effect that would naturally be supposed, for the reason that a very large portion of it is an under-run, rather than at the surface, and we have got to consider these matters from the surface conditions, that is, raw sewage from surface conditions rather than under-run, and the same is true of the under-run at the Narrows; the solution is not the same as to the volume of the under-run, it is the volume of the surface——

Col. Knight: You are speaking of an under-run: Do you know the extent of the under-run?

Dr. Jackson: I know it is a strong under-run.

Col. Knight: Do you know how it affects the surface?

Dr. Jackson: I know that the under-run is of comparatively clear water, and that the sewage is at the top,—on the surface——

Col. Knight: Do you know how far the under-run tide water goes in the Hudson river?

Dr. Jackson: I know it goes a long distance up the river.

Col. Knight: Do you know how deep the under-run is in the East River?

Dr. Jackson: No, sir.

Col. Knight: Then, how can you say its condition?

Dr. Jackson: From the conditions apparent in the appearance and in the position of the sewage itself.

Col. Knight: If the waters of the East River have got to go over a shoal—as it does—varying in depth from thirteen and a half to eighteen feet, how does that bear out your statement as to the under-run?

Dr. Jackson: I have made an examination by solution, for instance, of the amount of chlorine in the water of the under-run, and the difference from the surface is very material; if you go down just below the surface, it is one-half that at the surface,—and you get a considerable difference at varying depths, in the salts, and we have made a cross-section of the chlorine in the Hudson river, and we have found the fresh water and sewage practically all at the top, and that the salt water flows out underneath.

Col. Knight: Then, this precipitation which you say takes place of this matter in suspension because of the specific gravity,—that you believe is all on the surface, in the fresh water?

Dr. Jackson: Very largely at the top.

Col. Knight: Then you say something about this matter going back into the salt water, and being precipitated by the salt water, insolution, with an increase in the specific gravity?

Dr. Jackson: The fresh water is at the very top where the sewage is discharged into the salt water at the outfall, it boils right
190 up to the surface, and above the surface, then gradually becomes quiescent, and the part which precipitates comes in contact with the salt water?

Col. Knight: When you spoke of the volume, as to so many parts in a million, the dilution was to be all by water?

Dr. Jackson: All by water.

Mr. Child: May I have the privilege of presenting, as part of the case of the petitioners, certain extracts which I have caused to be made from the United States Coast Survey Reports?

The Chairman: Do you wish it to form part of the record?

Mr. Child: If I may.

The Chairman: That will be done.

(The following was submitted):

"Extracts from United States Coast Survey Reports:

In our opinion the conservation of ample channel ways at Sandy Hook is due in some measure to the tidal circulation which the Hell Gate entrance permits. This circulation is the life-blood of the harbor, cleansing the channels from the silts of its rivers, as well as from the sewerage of its cities, and even sweeping the sands from its grand avenue to the ocean.

New York Harbor is visited by two derivations from the tide wave of the ocean, one of which approaches by way of Long Island Sound, the other by way of Sandy Hook entrance. These two tides
191 meet and cross or over-lap each other at Hell Gate; and since they differ from each other in times and heights they cause contrasts of water elevations between the Sound and the Harbor, which call into existence the violent currents that traverse the East River.

Extract from U. S. Coast Survey 1867, pp. 158 and 159.

Two tide waves visit New York Harbor, meeting and overlapping at Hell Gate.

(2) Near the meeting point of these two tides the observed heights and times of the compound tide are intermediate.

(3) The currents of Hell Gate are called into existence by the variations in the relative heights of the Sound and Harbor; their epochs have no direct relations with those of the local tide, or its components, and their velocities do not depend upon the local rates of rise or fall of tide.

(4) The current flowing westward through Hell Gate occupies a greater section than that flowing to the eastward, because the former prevails during higher stages of the local tide than the latter.

U. S. Coast Survey, 1867, p. 161.

Although the tidal currents of New York, especially in the East River, appear to move to and fro with ebb and flood in monotonous repetition, like the swing of the pendulum, there is a net gain, under ordinary conditions of river discharge to the westward, i. e., a perma-

nent transfer of water from the Sound through the Harbor
192 and out into the ocean over Sandy Hook Bar. This state-
ment, if true, involves so many consequences affecting the condition of the Harbor (its navigation and its improvement) that I have put it in the form of a proposition to be demonstrated, first, from the most general relations of the Sound and Harbor tides, as oscillations of the sea "interfering" at Hell Gate; and second, from a strictly inductive study of gaugings made by different observers at different dates. I shall show that it ought to be theoretically, and then show that it is true practically.

U. S. Coast Survey, 1886, Page 409.

The peculiar quality of the East River current as compared with the free tidal current is that the former is a gravity stream, namely it is water running down a slope, as in a fresh water river.

U. S. Coast Survey, 1886, Page 410.

Although the Hudson, and other rivers flow into New York Harbor, and slightly raise its level, the conditions illustrated in our diagram are very nearly realized in the Seasons when the fresh water discharges at a minimum. One of these Seasons is the Autumn; the other is mid-winter when the land waters are ice bound. At such times the greater velocity being westward, and the greater depth of water being that of the westerly flow, there is, as a net result, a circulation of sea water through the Harbor from the Sound to the Ocean. In Mid-Winter this circulation renewing the water before it can get chilled, and lowering the freezing point by mixing sea
water with the river discharge, serves to keep the port open
193 to commerce. One may form some estimate of the value of
the four degrees difference of the freezing points between sea and river waters when it is remembered that in severe Winters Halifax, Portland and Boston have not closed before Philadelphia or even Baltimore.

The indirect value of this influx from the Sound during the dry Season lies in the partial supply of the underrun of sea water which occurs when the head of the river is insufficient to counterbalance the greater density of the sea water. We do not find this under-run (or preponderance of inflow) at higher levels than the deepest channel beds of the bar except on rare occasions; but one may easily see that the withdrawal of the influx from the Sound would cause the bar to rise and work inward. The fresh waters that enter from the Hudson and other streams play an insignificant part in the physics of the Harbor; but the circulation of the sea by way of the East River, although small in quantity, is the element which determines the superiority of New York Harbor over nearly all the sand barred inlets of the World. It is this circulation which keeps the port open in Winter and sweeps the sand from its threshhold.

U. S. Coast Survey, 1886, page 411.

The whole amount of water which flows into the New York Harbor in the course of each tide through the East River is sufficient of

itself to raise the water of the Harbor by one foot and one tenth.

The ebb commences two hours before the turn of the tide in
194 the East River and during these two hours the flow is toward the East River instead of from it. Next the amount of flow into the Harbor must be proportionately diminished and reduced to nine tenths (.9) of a foot. Now the Harbor at high tide has four and two tenths (4.2) more of water in it than at low tide, which runs out during the ebb, together with the flow from the Hudson, which is about the same as that of East River. The whole of the flow then through the Narrows which is independent of East River, corresponds to five and three tenths (5.3) feet in elevation of the surface of the Harbor, and this is the amount which would run if East River were to be cut off. The additional nine tenths (.9) of a foot which arises from East River gives a total of six and two tenths (6.2) feet as representing the flow through the Narrows and over the Bar. If the East River were cut off, the corresponding decrease in the flow of water would involve a proportionate decrease in the water-space over the bar or a reduction of the depth of water upon the bar of about three feet and a half. Such is the measure of the importance of East River to the preservation of the entrance to New York Harbor. The loss of this river would involve a fatal injury to the Harbor and any obstruction to its flow or reduction of its capacity must be proportionately injurious.

U. S. Coast Survey, 1871, Page 110.

Computations made upon the observations at different depths in 1858 gave for the discharge of the Hudson, at the close of the set

Season (1st June), 6,038,000,000 of cubic feet, and at the
195 close of the dry season (September) 3,360,000,000. Our more extended observation of 1872 (October) give nearly equal in flow and outflows amounting to 4,511,000,000, which is about the mean of the two gaugings of 1858. Now this added to the ebb volume of the East River, which was 4,383,000,000, gives 8,894,000,000. If to this we add the Harbor tidal prism 17,862,000,000, (which includes Newark and Raritan Bays, and the Kills), we have 26,756,000,000 of cubic feet. The gauging across the mouth of the Harbor from Sandy Hook to Coney Island gave, from observations of 1858, an outflow of 27,663,000,000 of cubic feet, which is only about two and one half per cent. more than the preceding computation. * * * Without claiming that all the water which comes in through the East River goes out over the Bar, and aids in the scour of its channel, I think this computation authorizes us to regard the East River stream as too important to be treated lightly.

I must add one general statement concerning a harbor with two or more outlets. It does not follow even when such a Harbor is visited by only one tide that there is a disadvantage in having more than one pathway to the sea, on the contrary a majority of the first class harbors of the world have several. Among sands it is not wholly upon the strength of the current that effective scour depends, but upon the power of these to dispose of the material advantageously. Equal and opposite tidal currents, however strong, cannot remove

the bars of our southern inlets, because in the short period of
196 six hours the very slow dune-like movement of the sand has not carried it beyond the influence of the adverse stream with which it works back to its old place; but where the ebb and flood are unequal, the material is swept entirely away from the mouth of the harbor. Now, with harbors of two outlets, it often happens (and I speak here with plenty of observed data at my command) that one channel is more favorably situated for discharge than the other, so that, in effect, there is a circulation in at one door and out at the other.

U. S. Coast Survey, 1871, Page 118-119."

Mr. Dean: Captain Parsons, who spoke yesterday, and who was formerly president of the Maritime Exchange, would like to add a little further to what he said.

Captain Parsons: Mr. Chairman and Members of the Board, in my desire to be explicit, and not occupy valuable time, I omitted some things that it was desired I should refer to. One of those was the effect of the sewage upon the metal on the bottoms of wood vessels loading in localities where the water is perceptibly polluted, say, for instance, that at Newtown Creek. Vessels going into Newtown Creek, and loading with oil, have frequently—with a new coat of metal, have frequently been obliged to re-metal their vessels at their destination on account of the metal having been perforated by the chemical action of this polluted water. So much so has this prevailed and to such an extent that frequently merchants in chartering freight vessels to load here have excepted Newtown Creek
197 from the privileges of the parties making the charter as to the parts of the City where vessels might be loaded.

Another was that, of the amount of expense incurred in dredging out the piers and wharves, caused by the deposits, made annually, in 1905, I must speak from memory because I have mislaid the document which I had secured, in 1905, over $800,000.00 was expended in dredging the slips and wharves just on account of this deposit made from the matter contained in the water where there was no action of tides, and this was very largely augmented by amounts expended by private individuals and for private wharves and piers, which must be done by themselves, in order to enable them to receive vessels drawing a reasonable draught of water.

The question of carrying the sewage directly to sea, which has been a prevalent opinion, until this matter was discussed a few years ago, has been very conclusively proved to be an error from the fact that the current—for instance, objects spread,—started from the Battery, even on the first of the ebb tide, will not reach the sea, but when in the lower bay, down within four or five or six miles of Sandy Hook, will meet the flood tide and be deflected into the bays, that which is further up, into the lower or Gravesend Bay, and that in the lower bay takes a circuit and finally comes back up through the Narrows again into the lower Bay.

I referred yesterday to the filling up of channels across
198 which the tide flowed rather than through them directly. This, of course, occurs where the channels are shallow, where

they are used mostly by our smaller class of vessels and so largely has this prevailed, that some of the anchorages used by this small class of vessels, such as the bay into which the Gowanus canal enters, the charter has found have been shoaled to such an extent as to almost practically destroy their usefulness to owners of vessels who have been formerly in the habit of anchoring in those places.

I was asked in reference to the apparent quantity of sewage in New York Bay and in the lower Bay, out where it could be seen. I desire to say that in my personal connection as a navigator in this Bay and in this Harbor, that it is not much in evidence in the stress of the current. That part of the harbor and bay which is used by the larger vessels it does not appear except the lighter material which floats on the surface. I have seen a dead horse make excursions up and down the river until he finally decided to locate himself somewhere along the South shore of Raritan Bay, but, ordinarily, the sewage is not much in evidence: but it is in the water and deposits itself along the shores. I have noticed upon a comparatively flat or sloping beach that the largest amount of the deposit was at the point of high water, but that it prevailed all the way down this sloping beach until it reached the flat surface, diminishing in quantity, usually, that there was more of it on the surface, but that it was
199 continually settling wherever the water was not in action.

In making the statements which I have made yesterday and to-day, I make them, not so much as an expert as from the viewpoint of a practical observer, and coming in contact with these interests to which I have alluded. The questions to which I referred yesterday, of its affecting the paint of vessels, that also shows very plainly over the painted surface as there will be a well-defined waterline derived from contact with the surface of the liquid around the vessel the paint of which is light-colored enough to permit it to be shown or which can be readily discovered even in black paint. I believe that is all.

Col. Ruffner: I want to ask you one question, if you please: What, if any efforts have been made by the municipal authorities to lessen the amount of destructive material poured now by the sewers into Newtown Creek, and what difference has that made?

Captain Parsons: I know that some efforts have been made; I know that the question has been very thoroughly discussed from time to time but up to the present time I know of no material improvement. I know that one year ago we had a vessel of about one thousand tons capacity that was painted white inside, that is all her waist and houses, etc. were painted white, and she went into Newtown Creek to load, and her captain requested me to go over and see the vessel because she was in such fine condition. I went over when he had been there two days, and the vessel, all her white paint, had turned almost black and there was nothing about
200 the appearance of the vessel which would invite the inspection of one who felt any interest in her. That, I will say, was just about one year ago.

Col. Knight: I would like to ask, in connection with your re-

marks about that, I would like to call your attention to this extract from the New York Bay Pollution Commission report: "That the reduction in the numbers with the depth is striking and indicates that most of the sewage and other decomposible refuse with which the bacteria were associated was floating around at the surface and not mixing uniformly with the water." That is from the report of the Pollution Commission of New York City.

Captain Parsons: Well, I remember reading that document.

Col. Knight: But you disagree with that?

Captain Parsons: I disagree with that to this extent—as I said,—but there is more of it manifest upon the surface; that is, more of it deposited at the surface of the high water, yet it prevails all the way down as far as you can see it where the water leaves the ground.

Col. Knight: Well, if you could judge by simple figures, the difference between five feet and forty feet is the difference between one hundred per cent. and twenty-five per cent.; that is simply the report—taking those figures for it——

Capt. Parsons: A vessel that is so unfortunate as to be sunk in those waters anywhere around where Gowanus enters the bay, will immediately commence to accumulate a deposit of sediment
201 and the expense of the removal of that sediment from the vessel is very often equal to the expense of raising her, so thoroughly has this deposited itself all over the inside of the vessel, adding greatly to the weight of the vessel and making the raising of the vessel that much more difficult.

Mr. Dean: Mr. Chairman and Gentlemen, the next speaker we have to offer is Professor Landreth of Union University and dean of the engineering school there and who, for ten years, was consulting engineer to the New York State Department of Health, besides a great deal of other experience. He has not prepared a set speech and it may be found convenient, to jog his memory, if I may be permitted to ask him a few questions as he goes along in the stages of the questions or subjects we expect him to talk on.

Prof. Landreth: Mr. Chairman, I have been asked to say at first a few words concerning an outline of the history of the activity and the position which has been taken by the State of New York with regard to the comprehensive question of the sewage of this Metropolitan district, regardless of State laws, not only as a proof of the activity of the State of New York and in its efforts to solve this matter comprehensively and effectively, but also as a basis for just one or two statements I wish to make concerning my personal observations in the Harbor.

In the year 1903, I think it was, the State of New Jersey,
202 by the Passaic Valley Sewerage Commission, first proposed to discharge sewage into New York Bay. At that time the State Commissioner of Health of the State of New York determined to investigate the fact, and, on inquiring, concluded that it was a matter of sufficient importance to draw it to the attention of the Governor; which he did. The Governor at once concluded that a commission of inquiry was desirable and a bill was accordingly, at his request, passed by the legislature of that year, providing for the

establishment of a New York State Commission, or, better, called the New York Bay Pollution Commission having for its object principally the examination of the relation of the proposed sewerage discharge from New Jersey into New York Bay and its probable effect on the commerce and navigation of the bay, as well as its sanitary relation.

On studying the question for a year or so, that Commission, first, reached the conclusion that it was undesirable that that sewer should be constructed; secondly, that the question was not a small one, and that it was not confined to the case of the Passaic Valley sewer, but that many other problems were concerned intimately with it, first of all the problem of the disposal of the sewage of New York, Greater New York and, as a corollary to that, to dispose of and purify the sewage of the metropolitan district; and that Commission reported; in its report it recommended the establishment of a commission of wider power which should coöperate with a similar one from the State of New Jersey to study the matter in a comprehensive way,
and to reach conclusions as to the ultimate disposal of the
203 sewage of the entire district so that whatever efforts should be made for the adoption of such plans should be made along comprehensive lines and should not result in the throwing away of useful funds and efforts, but in the correction of abuses.

Thereupon the State of New York provided a second Commission, the term of the first having expired, after, in fact, having been extended by request of the Governor, for a year to take the matter up more fully, and in the latter part of 1905 the State of New York established a second Commission, called the Metropolitan Sewerage Commission of New York, and while that was a Commission established by the State, the expenses of the commission were to be paid by the City of New York and the appointments were made by the Mayor of the City of New York, and that Commission commenced its inquiry in 1906, and is still in existence.

For the first, I may say that I was a member of the New York Bay Pollution Commission, and, also, for a year and a half a member of the Metropolitan Sewerage Commission. I say that simply to explain my reason for appearing before you and stating these facts.

Now, the efforts of the State of New York to coöperate with the State of New Jersey have not been satisfactory. An invitation from the State, through the Secretary of State to the Governor of New Jersey to have a similar body appointed resulted in the matter being referred by the Governor
204 to the State Board of Health of New Jersey, and no satisfactory coöperation ever resulted from that Board, so that the State inquiry as to the ultimate disposal of the sewage of the entire district has been carried on by the two States distinctly and independently, without coöperation So much, Mr. Chairman, as the basis for the observations which I am to refer to.

The question as to the swing of the tides and the swing of the sewage borne above them in the Harbor has been mentioned. Floats placed in the harbor at different points at the beginning of the ebb

tide, make trips of different lengths according to the state of the tide, whether it is neat tide or spring tide; also according to the direction of the wind, although precautions have been taken to eliminate as far as possible the influence of the wind, that has not been fully successful, so that the lengths of the runs are not entirely sustained,—they are modified or disturbed by the effect of the wind. They, usually however, may be said to represent the flow of a float of from ten to fifteen miles, consequently the flow of the flood for that distance. Floats have been placed at the Battery at the beginning of the ebb and have passed out as far as Sandy Hook. At other observations, the floats have not gone so far. Similarly, floats have been placed at Sandy Hook which have come up above Robbins Reef, and where observations have been made——

The Chairman: That is on the flood tide?

Prof. Landreth: That is on the flood tide, yes, sir; and in
205 some instances they have shoaled on the shore. The swing of the tide does occur. These observations leave the progression, besides, towards the sea; that is, the movement is clearly towards the sea, but it is by no means an overwhelming one.

These observations, coupled also with observations of the density of the water as determined by current determinations, indicate that about one-half or something less than half of the water which goes out of the Narrows never returns; that the remainder is the same water which went out. That fact is, I suppose, largely accounted for by the fact that the sea-way beyond the bar is not an open sea entirely but is confined between the two lands at right angles,—the Jersey shore on the North shore, of Long Island shore Eastways, and it disappears into that, acquiring a large standard figure of the flood tide drawn up in the same way and returns in part the same water that went out on the ebb.

Concerning the matter of deposit, the borings that have been made,—a good many borings have been made on the bottom of the harbor by apparatus designed for bringing up samples not only from the surface but from several points below the surface simultaneously, and these borings show very general deposits of mud, largely organic in appearance and, as far as can be detected, it has the organic contents, all the essentials of organic sewage which has passed through a fairly advanced stage of decomposition and some of it having, at last, reached the mineral stage, where it is generally similar to natural mineral material and it all contains the
206 characteristic sewage indicator, the B colae comus. At a depth of from six to eight feet, as I recall—I am speaking from recollection merely—I am not positive how deep the B colae is observed in the mud, it is very general, however for the first foot or two, in fact in some cases increasing frequently as the distance into the mud is penetrated and rapidly diminishing below that point——

Mr. Dean: Professor, what would that B colae show?

Prof. Landreth: The B colae would show original sewage or animal contamination.

Those, gentlemen, are much better observed where—that is I speak as to the phenomena—on the inner slope of the bar at Ambrose

Channel, and the observations which were made at the available places, indicated, as you of course know, quite a large amount of organic matter, of harbor sludge or harbor deposits has formed on the inner slope of the bar. Borings from there involved a cross-section of the bar where the sand is fairly clean, to a depth of eight to twelve feet on the inner point of the slope and diminishing then up to the normal shoaler flatness further up the Bay, suggesting a possible explanation that in the efforts of the material in going back and forth and lying close to the bottom, still moving partly in the sand wave, to reach the sea, but practically moving back and forth in the same place, partially influenced by the current, somewhat will accumulate on the bar.

I should like to add only one or two words to the exposi-
207 tion of the Boston construction and the conditions there as compared with New York, which Dr. Jackson very clearly set forth, and that is, to emphasize the fact that New York has one outlet to the sea through which sewage may pass, and doubtless a remote one through the East River channel, whereas Boston has five or six, contributing, therefore, to a much more effective mixture of sewage with water in the case of Boston than in the case of New York. I should say that doubtless very little of the sewage of New York Bay does pass out through the East River; the borings into the channel of the East River and all the analyses that were sent to us showed a practically clean bottom. No deposits, practically, were found in large portions of the channel of the East River.

Mr. Dean: What would you say with reference to the proximity of the sea, at the Boston outlet, as compared with the proximity of the sea at the New York outlet?

Prof. Landreth: I should call it open sea just beyond the islands, in the case of Boston outlet; it is so cleanly swept by the winds and by the ocean movements there, and not at all land-locked as in the present case, as it is but a short distance from the margin or border of Boston harbor out to the open sea; of course, the depths are not as deep as they are farther off coast, but there is a clear and undisturbed sea movement, both of the waves and of the winds and, as far as the purposes of dilution are concerned, it is practically adjacent to the sea.

Col. Knight: But as far as currents for removal are con-
208 cerned, not as good as the currents coming down East River?

Prof. Landreth: I am hardly prepared to say that.

Some comment was made yesterday as to the prevalence of activity in sewage disposal in this country. I have simply jotted down some of the sewage disposal plants built in the State of New York; a large number of other cities in the country are considering the matter; some have actually built plants; most are in course of investigation; the construction that has already taken place in this State of sewage disposal plants has been in the following places—this is not at all complete, and depends on my memory—At Albion, there is a sewage disposal plant for the State institution; Rockport has one of a municipal nature, constructed and maintained by the corporation; so also,

with Depew; so also with Doala; so also at Far Rockaway, and I might say that they are now investigating the matter with a view to the establishment of a plant at Sheepshead Bay; at Skaneateles they have a plant either under investigation or actual construction at the present time; the City of Hudson has a plant for the treatment of a portion of its sewage; I should say, that the City of Hudson has a State institution. The City of Kingston has been treating part of its sewage. The village of Saratoga has a complete plant for all of its sewage, which has been very successful; the village of Ballston treats all of its sewage; the City of Gloversville does a portion of its sewage and is investigating the question more
209 fully before embarking on a complete plant. The village of East Syracuse has a plant; the village of Auburn has one plant just about done and are advising as to the construction of another. The City of St. Louis, as you may know, is considering this matter. Of the remainder of the cities,—I may say that there is a number of small institutions and villages, smaller than those I have mentioned which have this matter actively under consideration or are actually constructing plants. Thank you, gentlemen.

Mr. Dean: Professor, with reference to the tendency of the sewage to rise as soon as it comes from the opening of the sewer into the bay, and then its future course, taking up the question of sedimentation; what would you say on that?

Prof. Landreth: Well, as a matter of observation that sewage does rise on its discharge from the sewer into the bay; it is a matter of speculation as to what happens then, but it is a matter of observation that sewage sludge is found on the bottom; we can only conclude that it must have been deposited after having first come to the surface; we know that some of the material does deposit at once,—the mineral portion; it is a fact that the sewage does float and does deposit, and where these conditions predominate there are two complaints, the surface complaint and the bottom complaint.

Mr. Dean: Then, Professor, what would you say with reference to the percentage of solids, organic and inorganic, in sewage
210 in solution as compared with that in suspension, and the possibility of the removal of either by any method?

Prof. Landreth: Ordinary sewage will usually show a larger proportion of its solids in a state of solution; I would say, from fifty to seventy per cent., will be in solution, and, sometimes, the percentage is higher than that, and the remainder, from twenty-five to fifty per cent., will be in suspension.

Now, as the action of sea water, like the action of other precipitating channels may be, and in many cases is, to change the state of some of the dissolved matter into suspended matter, by rendering it insoluble, and causing it to precipitate.

This is markedly the case in artificial experiments to determine the effect of salt water, and it is exactly the case in the sewage of Worcester, Massachusetts—which is an iron-manufacturing town, that is, its interests are very largely concerned with the manufacture of small iron products, and many of them employ the galvanizing processes, in which the thickening of the iron is part of the opera-

tion. The thickening is done by the use of sulphuric acid, and the effect of the operation, besides thickening the iron, is to produce a residual sulphate of iron, which is a precipitating chemical.

The action of that chemical, as it is discharged into the sewers, is shown in the results of the tests, in the sewage plants there, in which a larger portion of the solids which are in solution, are
211 converted into solids in suspension, than is the case in sewages where this precipitating chemical is not present.

Manchester, England, is a somewhat similar case, but to a lesser degree. Manchester has some industries similar to those at Worcester.

Col. Knight: Do you know who were the engineers for the State Sewerage Commission, about 1902?

Prof. Landreth: Of New York,—or New Jersey? I have forgotten.

Col. Knight: New York?

Prof. Landreth: Of the State Sewerage Commission? I have forgotten.

Col. Knight: I have an extract here of the report of that Commission, which shows, among others, Messrs. Rudolph Hering,—J. J. R. Croes,—as engineers of the State Sewerage Commission of New York. Now, you are in a position to know something as to the reputation of engineers, are you not?

Prof. Landreth: Yes, sir; somewhat.

Col. Knight: Are you sufficiently posted to pass upon whether the reputation of those men is above the average as experts on this subject?

Prof. Landreth: Decidedly above the average; yes, sir.

Col. Knight: Decidedly above the average; their opinions should be given weight above the average?

Prof. Landreth: I should say above the average.

212 Col. Knight: Now, this is taken from their report (Reading):

"The sewage should, therefore, be partially purified: that is, as far as it is practicable, by works on the Newark Meadows, before being discharged into Newark Bay, or, it must be carried five miles further, and discharged in its raw or crude state, into deep water of the upper bay of New York, where there is a large volume of water and a strong current to insure thorough dilution and inoffensive dispersion. * * * The outfall of the sewage would leave the shore at an elevation of about twenty feet above high water and extend about two miles into the bay to a point North of Robbins Reef ledge, practically in the centre of the bay, in the vicinity of which the channel is seventy feet in depth."

That is the statement then, of those men, whose reputation is far above the average, and are to be given, in the expression of their opinions, credence above the average statement——

Prof. Landreth: Their reputation, I think, is far above the average——

Col. Knight: Well, have you anything—do you care to say anything to gainsay that or in opposition or in refutation of it?

Prof. Landreth: I do not wish to question the good judgment of men who have seen the service and who possess the ability of those engineers; it is sufficient for me to say that they were engaged by and were reporting for and in the interests of the Passaic
23 Valley and not of New York or the entire district. Just how far they took into consideration, in an impartial manner, the conditions and effects on other communities and other States, I am not advised. I infer that they gave that some consideration.

Col. Knight: You have nothing, then, definite, to advance in argument against that statement?

Prof. Landreth: Simply that I could not agree with that statement as to its probable effect on New York harbor conditions; looking at it in a broad and large sense, without regard to State lines at all I do not consider (and I do not offer my opinion as equal to Mr. Hering) I do not consider, myself, however, that it is a desirable thing to discharge sewage in the form proposed into New York harbor. That is my view; that is just my view, based on my observation and experience; however, I do not suggest that it has as strong weight as that of the New Jersey engineers there stated.

Col. Knight: But you admit this part of it——

Prof. Landreth: That part is a matter of opinion——

Col. Knight (continuing): You admit that part of it is a matter of opinion; but you admit that there is a large volume of water and a strong current to insure a thorough dilution—would you admit——

Prof. Landreth (interrupting): I would admit that there is a large volume of water and a strong current; but I am not positive that it does always insure "thorough dilution."

Col. Knight: You are not positive about that?

24 Prof. Landreth: No, sir.

Mr. Dean: Mr. Chairman and Gentlemen: With reference to the last point which you brought out, about the difference of opinion among the engineers, as Professor Landreth would not wish to contradict the opinion of all those gentlemen, with your permission I would like to read a paragraph of the opinion of Professor Allen Hazen: That extract is as follows (page 28):

"With regard to the Robbins Reef outlet, such a diversity of opinion exists among the engineers as to the probable nuisance that would be created by the Passaic Valley sewage if allowed an outlet at this point, that it would be advisable to have the combined action of New York and New Jersey sewage commissions to determine whether this outlet would be practicable."

And, another quotation, a short quotation, on page 93 of the same report:

"It must be admitted that New York is better off without the discharge of New Jersey sewage. The discharge of sewage will tend to pollute the Bay locally. There will be an appearance of sewage for some distance around the proposed outlet, and this outlet is near the main channel up the harbor. There will be some odor, and grease from the sewage will smoothe the waves and show its presence

over a considerable area. To a certain extent these phenomena are disagreeable and objectionable, and if New York could compel them to build the sewer or dispose of the sewage without damage to others, it is clearly for her interest to do so."

215 That is the opinion of one of their own engineers.

Mr. Riker: Won't you read the next sentence?

Mr. Dean: Shall I read the next sentence, that he wishes me to read?

Col. Knight: If you please.

Mr. Dean: At the request of the attorney for the petitioners, I read:

"New York is now putting practically all her own sewage into the harbor."

And that is a point which I did not wish to touch on, but, since they have brought it up, and with your permission, I would like to say a word on that point: The conditions are not at all similar between the deposits of the sewage of New York City and that of the proposed Passaic Valley sewage, for this reason: that the sewage from New York City, including Manhattan Island and the other boroughs of Bronx, Brooklyn or Kings, Richmond and Queens, finds its way into the water along an immense shore-line through a great many sewer outlets which have been counted and, as I recollect, number three hundred and sixty; this allows an immense amount of dilution with the water contained in the different rivers and it furnishes an entirely different example than where an immense amount of sewage is discharged through one opening in one particular place.

Assuming that there is, and will be, an immense volume of water passing over the Robbins Reef outlet, for a certain area the sewage, as we have heard, will tend to rise, and cannot possibly mix

216 with the immense volume of water which is at that outlet, and would result in this sewage passing out and spreading out over the surface of the entire width of the channel.

Referring back to the disposal of the New York City sewage, we must consider that the sewers of New York City have been constructed during a long period of time, ever since New York City was a small village; and it is only in the light of recent discoveries and experiments in sanitary science that methods have been discovered for disposing of sewage, and that many different plans have been considered for disposing of the sewage of New York City, and that some plans have been discussed and are, in fact, under very serious consideration at the present time, by which New York City can take care of its sewage.

Some two or three weeks ago, I had the pleasure of appearing before Governor Hughes in reference to the pollution of the Hudson River, on the request of some twelve hundred petitioners who were complaining, and Governor Hughes said at that time that it was one of the most important matters that had come before him during his administration, and that he hoped that some comprehensive plan would be devised within a short time to take care of the polluted condition of our rivers and our harbor.

I am also informed, by the State Commissioner of Health (Dr. Porter, who appeared here yesterday) that steps were being taken to amend the public health laws in New York State in this re-

It is quite true that the laws of New York are not, at the present time, sufficient to wipe out the nuisances which are now arising. Efforts have been made in this direction, but the laws at the present time are in such a condition that we cannot compel a municipal or individual interest to stop polluting the rivers or to stop polluting the harbor. All that the law permits, in this State, at the present time, is that no new sewers can be constructed without permission given by the State Department of Health, and Dr. Porter put himself on record here as to the policy he has pursued on behalf of the State to prevent further pollution of the waters of the State by sewage. He is utterly opposed to the construction of sewers in the future, and he has refused permission to sewers wherever he could do so; he is urging the cities, both large and small, and municipalities all over the State, to put in disposal plants.

When we consider that only fifteen years ago, the first disposal plant was in practical operation in New York State, we can see that this is only a recent movement, and that some time must necessarily be taken before the laws can be brought to a condition where they can, in a comprehensive manner, dispose of these questions.

At the present time, a nuisance may be taken care of by the local boards of health, but as Governor Hughes said, or intimated, the trouble with the law is that the local boards of health often fail in their duty owing to the fact that they are generally doctors or men who have other connections with the large business interests, and they do not wish to antagonize their clients or the local interests, and that the laws must be amended so that the necessary action can be placed in the hands of the State Department of Health—as it is in Pennsylvania—and that is the action we hope to take.

As Professor Landreth pointed out, action has been taken by this State looking towards some comprehensive coöperation in this matter of sewage disposal, with New Jersey. In 1904, the Commission of which he was a member, the New York Bay Pollution Commission, held two meetings with the State of New Jersey commissioners, but so far as reaching any conclusion is concerned, they have been without any result.

As I pointed out, the offensive results of the New York City sewage, are not the same as would be from this big sewer, as proposed. In the present light of sanitary science, there is apparently no excuse why such an immense big sewer should be built. Considering the two applications, it is estimated that the sewage of New York City amounts to five hundred million gallons per day. These gentlemen propose, as you know, to discharge, at the beginning, one hundred and twenty million gallons per day, running up to an average, as Mr. Harrison stated yesterday, of two hundred and fifty million gallons further per day, and they estimate a maximum capacity of

three hundred and sixty seven million gallons per day. Of course, that is the maximum; but the policy of this State, and, I might say, the policy of New Jersey, at the present time, is towards correcting these sanitary evils.

219 It must be remembered that the Passaic Valley Sewerage Commission is a local body, and is not amenable to the State Department of Health of New Jersey, in its action. I would like to add that the reports, which I gather from the newspapers are, that the State Department of Health of New Jersey has recently taken action against the cities of Riverton and Camden, on the Delaware River, and Phillipsburg, also on the Delaware, and Seabright, on the Shrewsburg, to compel those cities to stop polluting those rivers; so that the State of New Jersey has placed itself on record as being opposed to pollution, while this Commission, which is not amenable to any State Department of Health of any State whatsoever, is seeking, in its own way, to dispose of its own sewage, without reference to what the effect may be upon the surrounding country.

I would like, if possible, but the time does not permit, to go into the alternatives which they may take up if they choose; but I would like to refer to just one statement that Mr. Hering made at Montclair, on October 20th which I personally heard; that, if this trunk sewer were not to be constructed, then they could build a sprinkler and filter which would do the same work, and that that sprinkler and filter could not be smelt five hundred or six hundred feet away from it, and that it would be cheaper to construct that sprinkler and filter than it would be to construct the tunnel which would extend through this territory from the shore of Newark Bay and under Newark Bay, with the accessories, out to New

220 York Bay. He said that it would be cheaper to construct that disposal plant than to construct the other system,—the trunk sewer, although it would cost slightly more to maintain it——

Mr. Riker: That statement applied to Montclair only, as to the cost, on account of its location, and did not apply to the other communities who are concerned in this project——

Mr. Dean: I did not understand it that way——

Mr. Riker: Why, certainly, the question that was discussed was as to the cost to Montclair——

Mr. Dean: I will question Mr. Hering——

Mr. Hering: My statement was that we might have to consider the erection of a sprinkler plant in time——

Mr. Riker: The question being whether Montclair would come into this project with the other municipalities, and the chief question referred to was the price to that community, to Montclair, and Mr. Hering's statement was that the filter arrangement would be more expensive——

Mr. Dean: Mr. Hering, does that statement in fact conform to your recollection,—is it in conformity with your remarks then?

Mr. Hering: I am sorry to be obliged to differ with the Judge. I was asked to go out to Montclair, to go to a meeting of citizens,

there, to inform them what the plan was, of the Passaic Valley Sewerage Commission; what they were going to do, because most of them were in ignorance of the details, and part is correct, what the gentleman has said, that I said it will cost less money
221 to put in a disposal works to purify the sewage of the whole district, but it will cost so much more to maintain it; that, estimating, as we should do in every business into which intelligent business men embark, the sinking funds, depreciation, interest on the amount invested, plus operating expenses, the total real cost of the work is greater, not cheaper; that Montclair would have to pay more if her sewage were purified in a disposal plant in the Newark Meadows, than she would if the trunk sewer was built as proposed—that is what I said.

Mr. Dean: May I be permitted to ask a question? If the individual municipalities in this district build their own disposal plants, would it not be more expensive to them—would they not make money by joining in the building of this trunk sewer?

Col. Knight: The answer to that is?

Mr. Hering: The initial cost, where such plants could be erected at all, might be less, would very probably be less, but the cost of maintenance would undoubtedly be greater.

Mr. Dean: May I call the Board's attention to a paragraph or two in a letter written by Col. D. W. Lockwood, of the Corps of Engineers, U. S. A., dated February 2d, 1907, with reference to the disposal of the Bronx sewage? Shall I read these two paragraphs, or simply put the matter into the record?

The Chairman: Read it.

Mr. Dean: The letter—in a part of the letter, it says,
222 with reference to the Bronx sewer:

"The effect of sewage discharged into the waters of New York harbor is shown by material being removed at the North end of Ambrose Channel and through channels elsewhere. To be sure, this discharge has been going on for a long time, but it is increasing very rapidly, and before many years it will be found not only desirable, but imperative that some comprehensive system of sewage disposal other than that now in use be adopted which will keep the solid constituents out of the harbor, besides rendering innocuous the liquids allowed to run, as now. The proposed sewer will add but little to the present unsatisfactory sewage conditions prevailing and from the best sources of information available it appears that the quantity of solid matter which it will carry to the river will be comparatively small, at least for a number of years. It is therefore recommended that no objections be raised to its installation, particularly as it would be included in any general plan for reorganizing the sewage system to the New York harbor that may come up in the future."

I wish to add that the population which will drain into the Bronx sewer at the beginning would be at the rate of only from twenty thousand to forty thousand people, so that it cannot be considered as a precedent for discharging the sewage of the Passaic Valley into the bay.

With reference to another letter, a letter of this Board, dated, New York City, May 28th, 1897, at page 53 of the report
223 of the commission on the sewage disposal of the city of Paterson. This letter, of the Harbor Line Board signed by the engineers, refers to the refusal of a permit to discharge sewage into Newark Bay, at which time it was estimated, in the third paragraph on page 53, that the entire amount of sewage which would be deposited in Newark Bay would amount to seven hundred and fifty-five thousand gallons per day; and, in the next to the last paragraph on the same page, it reads as follows:—from the printed report of the engineers on the question of the sewage disposal of Paterson——

The Chairman: Is that signed by Col. Robert?

Mr. Dean: Yes, sir; Cols. Roberts and Raymond——

The Chairman: That was in 1897?

Mr. Dean: Yes, sir; and, of course, the conditions are worse now than they were then.

(Reading:) "The estimated annual deposit of six hundred and fifty thousand cubic yards of solid material in the lower end of Newark Bay, following the adoption of the proposed sewage system, would fill up the entire area of the Bay below the proposed sewer outlet, from bank to bank to the depth of about one-third of a foot annually if evenly distributed. As the existing average depth of the flats, except in the narrower width of the mud adjacent, is about four feet at mean low water, it is easy to see that it will require only a few years to make the proposed sewer system not only a public nuisance, but a serious obstruction to the navigable waters adjacent to the harbor of New York.

224 "The Board is of the opinion that, as a general rule, when it is desirable to discharge sewage or other material into tidal waters, it should be at points where natural deep water exists and not in the vicinity of artificial channels which require periodical dredging for their maintenance.

"Newark Bay is a land-locked tidal basin of considerable area, with comparatively small outlets, through which it will always be difficult to maintain channels of a depth adequate for navigation.

"The Board is of the opinion that it is not advisable to permit the use of such a basin as a receptacle for a large and constantly increasing amount of sewage.

"Even if the dilution of the sewage for which provision is now contemplated should be sufficient to prevent serious deposits, it is certain that the amount of discharge will rapidly increase and eventually produce shoaling in the channel.

"The Commission recognizes the fact that this sewage cannot be indefinitely emptied into the waters of the Bay, and that a time will come when other means must be adopted for its disposal.

"The Board concurs in the opinion of the District Engineer that the disposal of the sewage of the lower Passaic district in the waters of Newark Bay will be detrimental to the interests of navigation."

I wish to add that this subject was further considered by
225 the Military Secretary, Acting Secretary of War, as late as August 3d, 1906, the letter of whom appears on page 55,—it

does not state his name—of the same book, which I will not read, but it is to the same effect.

We have not attempted to estimate the entire solid contents of this sewage as will be discharged, and I simply wish to call to your attention that the average daily flow at the end of this period, at 1940, is estimated, as they say, at two hundred and fifty million gallons, which would be slightly over three times the amount they formerly proposed to empty into Newark Bay; and I also wish to add that if they are of the opinion that the sewage will be so clarified (that is the word which was used yesterday) in their proposed scheme, why should they go to the trouble and expense of building a tunnel under New York bay,—why do not they admit it into Newark Bay, instead of going to the expense of building this large tunnel? I think that the fact that they are expecting to build such a tunnel is an admission on their part that they would feel it to be folly to apply to this Board for permission to dump it into Newark Bay in the face of this report of the Board.

Col. Knight: Do you make no distinction between the physical conditions of Newark Bay and those of New York Bay? Of course, that has everything to do with the matter. The Harbor Line Board, whose report you have read, rejected an application for a discharge sewer into Newark Bay because of certain conditions,—do those conditions hold in New York Bay? As to artificial channels?

Mr. Dean: Of course, there are artificial channels in New
226 York Bay,—Ambrose Channel and other channels with which you gentlemen are much more familiar than I am, as a lawyer. We have had some testimony as to the amount of dredging occurring in slips and piers at the present time, and if a comprehensive scheme is fulfilled, to prevent New York City from the affliction of the offensiveness of this sewage, then the construction of this sewer would be a very great discouragement towards following out a comprehensive plan, and would, on the other hand, counterbalance any removal of sewage which New York City might be able to make of her own.

Then, the other reasons why these are to a large extent similar, is owing to the under-run which I admit is somewhat indefinite, and I can only refer your Board to the report of the Department of the Interior of 1886, or 1887, I think it is 1886, in which the subject of the underrun is considered. That shows that the water nearer the bottom of the Bay tends to stand still or, if anything, to move up towards the Hudson River and that while the current on the surface of the water may be going out, the under-run is coming up, and that the under-run under any conditions, even at the end of the ebb tide, does not go out as far or with as great velocity as the water does at the surface, which would show that the specific gravity—it is due to the specific gravity—keeps that water more at a standstill near the bottom, and that this stuff there, the sediment and the precipitants
from the sewage,—as the chemical and bacteriological action
227 takes place on the surface of the water, it sinks down into this water of greater density and washes back and forth on the bottom and settles near the bottom. Of course, the freshets in the

Hudson River would have a very large effect and tend to wash it out to a large extent, but in the late Summer or Early Spring, when the ice is still in the river, the water of the Hudson does not push the tide out as far, and that deeper, or underrun goes away up the Hudson River. That, of course, is all technical, but I am stating that as mere facts which I have derived from studying the different reports to which I have referred.

Col. Knight: Well, as regards the conclusions you can reach there, from studies of those different reports, you differ apparently with what we learned from the gentleman you asked to explain these matters to us——

Mr. Dean: Professor Landreth——

Col. Knight: You have had a statement from him as to the clear condition that the bottom of the East River is in, have you not? That was his statement, that it was clear?

Mr. Dean: Along the bottom of the East River?

Col. Knight: The East River; yes.

Mr. Dean: My impression from studying the different reports is——

Col. Knight: I only want his statement——

(The stenographer could not immediately locate in his notes that portion of Professor Landreth's remarks, and Professor Landreth was recalled.)

228 Prof. Landreth: I do not recall the exact form of my affirmation: I wished then to make it clear that the East River was the only spot where we found a clean bottom, in the harbor of New York.

Col. Knight: Now, then, in the report of the New York Bay Pollution Commission, they say the following: "From examinations of samples there, the water of the East River is shown to be very much more polluted, lately for many years than the waters of the Harlem or Hudson Rivers. * * * It was therefore decidedly more polluted". Consequently, in view of this statement, we would not expect that in waters which are more polluted, we would find, in that place, a clean bottom, unless you admit that there is some credit to be placed in the statements about the scouring power of those waters,—the preponderance of the ebb tide of the East River down through that channel.

Mr. Dean: I think that in explanation of those tests it can be said that those tests were made on the surface of the water——

Col. Knight: That is where you say this sewage is.

Mr. Dean: The bacterial action takes place, in a large preponderance, near the surface of the water, and as the bacterial action takes place, it decomposes this organic matter, which, as it decomposes, goes to the bottom.

Col. Knight: That is just what I say; you do not find it in the bottom, the current carries it away.

Mr. Dean: But the Department Reports will show, undoubtedly,

that there is a stronger current in the East River than there
229 is in the Hudson.

Col. Knight: Well, that water which comes down during ebb tide on the East River must continue out and does continue out.

Mr. Dean: I believe I recollect reading of the large body of water going through the Bay.

Mr. Ackerman: In this Hazen report, just referred to, I want to say I was secretary of the joint committee, and, in the clause quoted by Mr. Dean in reference to the appearance of the sewage for some distance around the proposed outlet, Mr. Hazen's deductions were made at that time on observations of the Moon Island and Deer Island outlets, the Nut Island outlet not then having been completed——

Mr. Riker: In Boston——

Mr. Ackerman: In Boston. And, furthermore, Mr. Hazen, at that time, had no plans of the Passaic Valley Commission; he was acting solely for Paterson, and was obliged to make his own observations, his entire observations, his own figures, from looking up the figures previously reported by the Passaic Valley Commission.

In view of the fact that Dr. Soper presented a paper yesterday, and Mr. Hazen's name has been mentioned, I wish to call the attention of this Board to a paper enclosed in this report (referring to book in hands of speaker) on the discharge of sewage on the New York side, being a discussion by Allen Hazen of a paper presented by Dr. Soper, to the Society of Sanitary Engineers of Boston, and on page 142: (Reading)—

230 "The quantity of water that comes into the New York harbor through the Narrows, and goes out again, if reduced to cubic feet per second, is a tremendous quantity; altogether, it represents a flow of over three cubic feet per second per thousand of population for one hundred million people. That is a pretty large population,—more than the present population of the whole United States, but there can be no doubt that, diluting the sewage from it, with this amount of clean, cool, sea water, and with the strong tidal currents which exist, would render it inoccuous and inoffensive."

On page 143 (Reading):

"Of course, it is also true that when New York reaches a population of twenty-five million, a great deal of it will be on Staten Island and on Long Island and so located that it will not discharge its sewage into the ocean through the barred harbor, and these computations that we previously make do not take into account the conditions of the lower harbor which are undoubtedly vastly more favorable for the dispersion of sewage, and so it looks as if it may be centuries rather than decades to the time when radical measures for purifying the sewage of New York City will be required."

I ask you to accept this report to the Board (proffers book, which is accepted by the Chairman, with thanks).

Mr. Lebkuecher: I desire to ask the privilege of the Board and the Government, as represented by the Board, to give us permission to refute some of the statements that have been made in
231 opposition to this application; for instance, the Boston harbor discharge was referred to and only the Moon Island discharge

of that City, whereas there are three discharge points in Boston harbor, and the one referred to is the oldest one of all, which has been in existence, as I understand, for over thirty years, and found to be inadequate, and newer ones have been installed on more modern lines—plans. Now, generally speaking, we all admit that it has been found that the sewage problem is one of the problems of the civilized world,—all over the world,—the civilized world, and it has been said that, fortunate are those communities who, located near the sea, where there can be a discharge of sewage by dilution. We fully understand—as a member of this Commission I desire the members of this Board to understand that this Commission has made a thorough study of all methods of sewage disposal and the trouble about the disposal of sewage is universal,—all over the world, except where it can be diluted in sea water.

This past Summer I made it my business to study sewage disposal works and observe them, and I have gone to Europe, and in England,—made it my business to see what is being done in that line, and, while theoretically, sewage can be disposed of artificially, through filtration or sprinkling systems, sedimentation, and all that sort of thing, I want to say that I did not see a single disposal plant that was theoretically perfect,—that is, up to the theory of the engineers of the disposal plants; these disposal plants were all
232 practically alike, all more or less of a nuisance; it didn't make any difference which system was in use, they were all more or less nuisances; sometimes they worked all night; sometimes they did not.

Now, in this matter of the disposal of the Passaic Valley sewage, our law allows each community to dispose of it as it sees fit,—to go into contracts with this Commission, and to make one job of it, or to dispose of its sewage as best it may.

We think, and it seems to me that it is very evident, that this section is a part of the metropolitan district; it gets its population because of the metropolitan district, and it seems to me unthinkable that there should be twenty separate disposal plants, one for each of those municipalities to be installed in order to get rid of the sewage.

The matter has been thoroughly studied, and I do not understand how the New York people can come here and ask the privilege of continuing the disposal of the sewage of ten times as many inhabitants in the bay and harbor of New York, and then object to the extra one-tenth from a community which is a part of this same district.

And, furthermore, we have made a study of it as to the question of pollution, and for that very reason it is that we want to diffuse it as much as possible; the idea is to have a large area on the bottom of the bay, with very many openings to give it ample chance of dispersion and assimilation.

As long as the population of that district was small, the
233 Passaic River was amply able to take care of it,—it dissipated it, or ate it,—for that is what water does with sewage if the pollution is ample; and we feel sure that there will be no perceptible pollution on the plans as outlined by our engineers.

I would like Mr. Hering to explain why some of the statements made by the opponents are not fully correct as far as the Boston situation goes.

Mr. Hering: Gentlemen: When I was here yesterday, I did not know that I would have to say anything about this matter, and I was absolutely unprepared, and I ha dan engagement last evening,—so I did not prepare a statement for you, but I will speak off-hand, as my memory recalls such things as have been said.

I, first, would like the privilege of answering Mr. Landreth. I would not like to have the Commission believe, for a moment, that my principles of life were not different from those which I am afraid you might infer from what Professor Landreth stated. I never engage as a partisan in any piece of work, whether I am testifying in court, or whether I am engaged by a municipality.

When I was engaged by the Passaic Valley Sewerage Commission to suggest to them what they should do here, I might have said,—"Discharge it just like Hoboken does,—just like Jersey City does, right out of the sewers," the way New York City allows it to be done. I did not. I, realizing that this was a community only theoretically separated by the State lines, recommended,—my
234 recommendation was that it should be put where it will not harm the City of New York or this great metropolis, although it required New Jersey to spend a good many million dollars more to do the work just for that purpose, and no other. That was my recommendation, and no other. I was just as much looking out for the interests of New York as New Jersey, although I had no New York position at that time.

I would also like to answer my friend, Dr. Jackson, who, I thinks, perhaps misrepresented himself in some respect to your Body, in speaking only of the Moon Island sewage disposal of Boston, and perhaps thus leading us to suppose that that was what is going to be done here.

I remember when the Moon Island plant was built; I know why it was designed just as it was; I knew the chief engineer very well, visiting the work while under construction. It was the best system then known to deal with this sewage, and also the least expensive one for that part of Boston. They all saw the objectionable features of that method of disposal, and the next opportunity they had, to put in the works at Deer Island, they used a very different method there: Why? Because better. They discharge at all times; they do not do as at Moon Island, start up after the ebb tide has begun, and where they partially purify the discharge as at Moon Island, we will say that it does discharge on the surface,—the effects are not so bad as some of the stuff that floats around the harbor of New York to-day; and I would like to say that I have been out there a number of times,—only a year ago again, and that was dis-
235 persed entirely, so that you cannot see it, inside of two hours,—although the surface is black appearing and offensive, especially after you get out a mile or two,—I think it is possibly all gone——

The Chairman: Where is that? Deer Island?

Mr. Hering: That is at Moon Island. Now, at Deer Island they discharge this sewage at all times; they bring it out and turn the pipe up, in an upward direction, quite near the surface, so that at low tide you can actually see the rise of the water, due to the forces of the discharge, raising the surface, and as it is quite near the surface, naturally you see it flowing over the surface there. That is not the right way to dispose of sewage; they realized that,—so, when they built the other work at Nut Island, they discharged it at the bottom, further down, so that it has a greater distance to come up before reaching the surface, and in my humble opinion I think it is an error, the way they have built it, because they have carried the whole pipe right straight out to the outfall, giving this fresh water sewage a velocity, I think of three or four feet a second to start right up to the surface, and, naturally, it comes up to the surface if it gets a push equal to that, and yet, notwithstanding this condition, thus added velocity, and the single discharge, it is not nearly as perceptible as at Deer Island.

I think that the method proposed here, which is to discharge it in small outlets for dispersion, is far in advance of anything at Boston, and will be effectual. Then, another matter, to obviate this velocity, this shooting up,—as has been stated,—the proposition here
236 is to discharge it horizontally, which is much better, because it shoots out at a velocity of about three feet a second, and now, discharged horizontally, it has got to come to a dead stop before it can move in a vertical direction, and then, with the vertical openings in the horizontal discharge pipes, there is nothing to give it a push upward, nothing to cause it to rise up; therefore, the tendency to go up will be much less here than in any of the outlets at Boston. Besides, we all know that a small stream will disperse very much more rapidly in the element into which it is discharged than a large stream. This you can see even if you have a pitcher of water, or, perhaps, a tank, and you squirt into it a stream of water, perhaps a quarter of an inch in volume, dirty water squirted into your receptacle, and you will see how very rapidly it is dispersed.

I think that the Moon Island proposition as mentioned here is not at all to be compared with what we are going to do, and even the other plants at Boston, which I have mentioned, I think should not be compared, and the effect on the surface of the water ought not to be compared with what you are going to have here, because of the reasons that have been stated, and the different methods of dispersion suggested.

The Chairman: You say that the sewage that comes out at Deer Island outlet has been treated before it is discharged?

Mr. Hering: Well, it is screened partially; and right there I might take up the question of screening again: The screens
237 there (Deer Island) I believe, are one inch apart,—I am not sure but I should like to state, in view of the fact that yesterday some weight seemed to be given to the fact that there was no specification of just how the sewage was going to be screened and how it was going to be settled; I would like to reply to that.

This matter of screening is a subject that has been studied very

carefully for the last two years; in Europe we saw all sorts of screens there,—wide ones, of an inch opening, down to a millimeter. Measurements, of course, have been made as to what that takes out, and there is not such a great lot of difference; the results vary from ten to twenty-five per cent. of the entire suspended matter.

Now, the finest screens that I have been able to find in use were in Europe, and we have, I think, one of the finest in the world here in this country, and they do not take out twenty-five per cent. of the suspended matter. Now, what is the difference? Is there a great difference between ten and twenty-five per cent. as regards this proposition? I do not think so. The difference is here: you must take out everything that is visible; everything that is large, and those are the screens that are proposed to be put in here, and all the screening used in Europe is that they take out all the larger matter,—there is no percentage there.

But, when you speak of the suspended matter in general, you must include, also, the very fine matter which goes through the
238 screen, and which is the bulk of the matter. There is another difficult point,—you might ask, how could that statement throw a great deal of light on the subject? That is, to be more definite about it, we have a difference here: we have the Paterson sewage, coming down twenty miles through the sewers, all broken up, yet going through the screens, in a different condition from what the Newark sewage would go. That whole proposition is so complicated that it can be worked out only after a good deal of study and observation of it, and so on, for which no funds have yet been spent, and which, I must remark, must bear some relation to the amount of dilution necessary at that time,—because we know the screens will do the work. That settles this point.

Now, about the question of sedimentation; that is a question that has never been settled because it was, in the first place, a question of funds, and rather a complicated study, and chiefly because the Commission thought your Honorable Body, or the Army, would designate how much of that sediment would have to be kept out, and that merely means making the tanks a little larger or smaller; that is all it means, and, in the estimate of cost, enough was put in to cover that, so that I do not see that that is such a great thing to be known before you can say whether this proposition is worthy of adoption or not.

I was asked yesterday to get some information on the solid matters: I have had but very little time to look up this matter, and you know that sewage is a very changeable matter. You cannot
239 give an analysis and say that that holds good for all cases. Now, take, for instance, the European and American sewages; our sewage is about twice as dilute, and sometimes three or four times as dilute as European sewage. I stated, yesterday, that the amount of suspended organic matter in sewage was one in five thousand. Well, I was not certain about it, and I did not wish it to be held down to that; and now I find that that is the English figure; in our country it would be one in ten thousand parts because our sewage is twice as dilute. That is the suspended organic matter,—that which

foals, or part of which foals. Then the suspended mineral matter. This must be determined by the fact as to whether you have a combined system or a separate system,—which is a very different matter. If you have a combined system, you get all of your street wash, and that is a great deal; that is mineral. The abrasions from the street and from the horses' hoofs and the quantity of iron is quite material, and dust, mineral dust, and so on. So, I am now giving you a figure for the separate system, because this is to be a separate system (although temporarily Newark and Paterson still have combined systems, but for their own interest financially they will have to change and get separate systems). In a separate system, the suspended mineral matter is, taken roughly, one in twenty-thousand, or, the dissolved mineral matter is about one in six thousand. Now, there, you have got a general composition of the sewage, but it is very rough, because you really should have the particular kind
240 of sewage that you are treating with, and that is the general average of American conditions.

Col. Knight: What was your third figure there,—the dissolved mineral?

Mr. Hering: One in six thousand.

Now, I have already stated that the proportion of solid organic matter which can be screened out varies from fifteen to twenty-five per cent; that is the solid organic matter that can be screened out, and that is all that will float in this case.

With reference to the sedimentation tanks, as I say, they have not been designed; they can be designed on the basis of whatever figure is given by the United States Government. For instance, let me say, if you build your tanks so as to reduce the velocity to about six inches per second—I cannot state now that that is the figure to be adopted, it is not settled,—you can get out from one-half to one-third of the deposit matter—six inch velocity per second in the sediment tanks,—six inches sediment. Now, that is the figure that has been used elsewhere, and it is about right.

Now, I want to say that what does not deposit will go on, and go into the river. That is so fine that it makes the water look dark. I have here some data about the observations that were made by the Commission for Additional Water Supply in New York some years ago,—in 1903, in New York, as to the attributes of the water in the Hudson River at Poughkeepsie, and when I say that the sus-
241 pended matter that is, the organic matter, is one part in ten thousand, I mean one hundred parts in a million. That is merely as a measure, because I am going to give you now some of the properties of the water of the Hudson River, coming down from Poughkeepsie to the Battery. They range, of course, from nothing, which is clear water, sometimes, to four hundred parts to the million, and that is four times greater than the amount of suspended animal matter that would remain in the sewage, or would be in the sewage discharged after this sedimenting—no, without the sedimenting—that, that is without the sedimentation; that is all that would remain in the water not sedimented, in the unsedimented sewage,—about

four hundred parts in the million; that is the maximum that I see here during the month of March.

The data runs from two hundred to four hundred, two hundred and eighty, and so on, so that we have this point in view, that the suspended matter is very fine, particularly after the sewage passes through the systems of purification, after being screened and flowing through the purification works, that it has no more suspended matter than the river carries with it into which you are going to discharge. The plans call for the putting in of a basin or basins to remove the putrescent matter, and this is provided for and is part of the present most economical system of sewage purification. In the discharge of this sewage there will be nothing floating—although it is dropped into the river in the New York City system—and there will
242 be no nuisance or offense, because the amount of suspended matter that is in this purified sewage and non-putrescent discharge, is no more than what comes down in the river, therefore not making the river worse than it is in any way.

Col. Knight: You say that matter is non-putrescent?

Mr. Hering: Non-putrescent—the modern system of sewage disposal,—if you care to hear it——

Col. Knight: I would like to know why, if it is organic, you say it is non-putrescent?

Mr. Hering: It is not altogether organic. The modern system, the cheapest system is, purely, aeration by means of spreading the sewage over a bed of stone, through which it percolates, goes around the surface of the stone, which is exposed. Now, if the stone bed is to be permanent, and not require cleaning, everything that goes in must come out; therefore, whatever solid matter goes in and forms, must go out; this is effected by means of a non-putrescent flush, and the resulting matter is called in England, humous; this, being introduced into a river, is likely to make it turbid. Of course, in the European or English rivers, the waters are more clear, and they settle this out, but in our Southern rivers, for instance, where the streams are all muddy, it would be — thoroughly settled that it would cause nothing worse than what is in the river. But it is the proper method of sewage disposal, and by its means you get your effluent absolutely non-putrescent. I believe thor-
243 oughly it can be done; it has been done in England, is done here at the present time in one system—but there are still a great many unknown quantities about this method, and we are not at all at the end of the book.

Mr. Kissam: Before this hearing closes, I would like to make a few remarks. I represent the City of Orange——

The Chairman: Mr. Hering has not concluded his remarks as yet; you will have an opportunity to speak.

Mr. Hering: I was asked, also, to give some data as to just what happens to the sewage, and how far it would travel up the river after it was discharged at Robbins Reef Light, and I have not been able to get the data to make all of those calculations, but what remains is pretty simple. If the sewage is discharged at Robbins Reef at low tide, then, when the tide comes in it will all travel up

stream, go up the Hudson River and the East River. Just how it is to be divided, I cannot say now, but, let us say it goes up the Hudson River to a certain point. I cannot tell you how far it is. It would be a little difficult question to answer that yet, unless experiments had been made to verify it. You know, of course—I will make that statement to your honorable Body,—water does not run up like the body of a wheel,—it runs up faster in the centre of the stream than it does at the sides, and faster at the surface than it does at the bottom, and, therefore, to make any prognostication as to just where that sewage would go, or how far it is going, is a matter that cannot be answered off-hand.

Mr. Lebkuecher: How long will it take to dilute the sewage so discharged?

244

Mr. Hering: I think it can be diluted so that you could not see it at all within perhaps—well, I make a guess now, based on rather long steady study and experience—a few thousand feet from the place where it is put in. I do not think you would be able to see it.

Mr. Lebkuecher: But in the experiments with the aniline dye water showed it went how far?

Mr. Hering: Well, we did not know how far it went because we did not see it at all; the aniline dye water we put into the water at thirty feet below, we never saw again, but as this was only a preliminary experiment, so to speak, we did not think—we were not prepared to make any further investigation, presuming it could be done at some future time to find out how it is going below. All we were interested in was how soon it would come to the surface.

Now in this proposed sewer, we propose to discharge at fifty feet below the surface, that is, on an average of about forty-five feet, and if it does not come to the surface at thirty feet it would probably not come to the surface if discharged at forty-five feet.

Now, I cannot say how far it is going, but the very fact that it moves up the centre—whereas all of the New York sewage is discharged at the sides,—the Jersey sewage being discharged at the centre would keep those two bodies of sewage somewhat separate, if they exist perceptibly, as I do not think they will by the

245

time they get up to New York. I do not know how far the sewage would run up. I have not been able to look that up in the short time that I have had. Now, let us analyze, somewhat, this question: Some of the matter that goes in at the outfall will probably be coagulated, if it goes down deep into a saltier water than at the top, but that whole question is not by any means clear. I think it has been misrepresented often. I am sorry to say that I believe my friend, Dr. Soper, yesterday fell into an error in presenting two photographs here, of which I merely heard, but which say that sewage—but which would lead you to infer,—or might lead you to infer, that that sewage, discharged down here at this outfall, would deposit more in salt water than in fresh water.

I do not know how my friend, Dr. Soper, made those experiments, but that is not the way things are going to happen here. In the first place, we take out the suspended matter, by deposition. We

ke out the screened matter that is not in that sewage that you
t down there,—that is taken out, and the deposition,—that we do
o is material as that is just we propose to take out,—that is not
a the sewage that the Passaic Valley Commission proposes to dis-
harge into New York harbor—that is taken out by screening and
ettling tanks, and, therefore, I do not think it is a fair inference
o judge from a chemical experiment in a laboratory, what is going
o happen there. We just must know what we are doing.

Now, I also want to say this: That, in Europe, where they are working pretty hard on these matters, I heard statements
36 from prominent chemists—I am not a chemist myself and I do not wish to have you, sir, take any of my opinions on chemistry as final,—I heard that the experiments that had been made there on this subject of precipitation in salt water and fresh water under proper conditions, and proper water, showed that there was more precipitation in fresh water than in salt water,—against what I have heard here to-day stated. Now, no less an authority than Dr. Fowler, of Manchester, made that statement to me last Summer, and I will say that, within a short time, perhaps a month or two, the Royal Commission of England, which has been working on this matter for I don't know how many years, it is years—made a report on the discharge of sewage into tidal estuaries. It is a large blue book about two inches thick and in it, I think, very nourishing reading,—it has a great deal of information in it, by the best engineers and chemists of England—Dr. Fowler is quoted in the report, as is Mr. Adney, and Mr. Leets, and other prominent engineers, representative people, and they got through with their report; I have not gone all through the book, but I am quite familiar with its contents, as I had consulted with a number of those gentlemen last Summer, and know about what the results are. I have read some of the conclusions they reached, and was much gratified to find that the Passaic Valley Sewerage Commission had, to some extent, anticipated the report in the recommendations which they had made.

Now, we cannot take this question as final at all, whether
37 sewage is going to coagulate we know, but just how much, is another question, there is still a good deal to be done. I anticipated, of course, that the Passaic Valley Sewerage Commission, in due time, would make the necessary experiments to find out all the principles necessary to make their work beyond criticism. Now, some matter, I said, would be coagulated. Some matter will be deposited on the beds. Now, what is that? That is chiefly, gentlemen, pretty near wholly, the street wash water that comes out in the combined sewers. Now, this has been shown in Europe very nicely in cities where they formerly had combined systems of sewers and discharged right into the rivers; they got their sediment, and afterwards they took the sewage out and purified it; they had the same black deposit; not so much, but it is that same character. Where does it come from? Why, it is the surface wash from the city. In New York it would be the street wash, the attrition, the dust that deposits a particle, it is that which does not

usually get into the sewer. That is all cut out except the decomposible matter there, those stable fibres continue a long time, decompose slowly. It is not like animal matter, which decomposes very rapidly. This organic matter, which remains a long time, those shreds and fibres, they go down.

Now, that deposit finally, when the velocity gets so light that they will drop, drops down, particularly when you get near the ocean,—the bar is formed practically of just such matters, and, where there is no such deposit, it is formed of suspended
248 matter that comes down the river from the fields and forests, and so on,—that forms the bar, so, only the suspended matter that remains in the sewers, and that is the deposit on the beds, and it is of that character nearly always. The other is consumed. It is eaten up, either by the gross animal life in the harbor, or it is eaten up by the bacteria which fill this water here, given the presence of oxygen; that is to say, the water must not be diluted so that there is not a sufficient amount of oxygen to nourish the bacteria which you need to eat that up, so that most of that matter is dispersed in that way. Some actually goes out to sea.

Now, there you have the whole list of matters and every one has some value. We did not know what—I could not give you any figure at all. One guess is as good as another, but that is a matter, a subject which I hope somebody who has money to spend will some day investigate and illuminate the scientific world on,—how those proportions really are.

There is another matter I have not mentioned: That is, grease. A good deal has been said about that. They said,—I think some gentlemen said, and I think, also in the paper, that we would be able to see a big black grease spot at Robbins Reef Light. It would be right in the line or route of boats to Staten Island, and would be very objectionable. Now, there is no doubt about it at all, that some grease will come down; some of it will be kept back in the settling basin no doubt, but a good deal of it will come down here without question, and grease rises to the top, being lighter than fresh water. It will go faster than fresh water, but I think
249 that matter has not been sufficiently tried anywhere to know exactly what it is going to do. My own personal opinion is that there is going to be a dispersion, and the appearance of grease in the harbor will be very slight. I do not think that you will see perhaps not one-fifth or not one-tenth more than the grease that now comes down on the surface from these New York sewers. Nobody complains of that. I do not think anybody will complain of the grease that will be caused from the Passaic Valley sewer. Besides, it is not offensive. You have all noticed, on the ocean channel, in perfectly still waters, you will see a great track where vessels have passed before. That very small amount of grease is spread out over a large area. So, to-day, when the water is still, you can see in New York harbor a great deal of grease now, but, as I say, it is not objectionable, it causes no odors, it is not offensive, but it is a feature that will be there just as it is to-day.

I wanted to say something which I think is apropos. Manchester

is a large city in England,—it is there, quite a little distance from the ocean. It got a ship canal from the ocean so as to have ships come direct to Manchester instead of trans-shipping goods at Liverpool. Liverpool is at the mouth of the Mersey, there is a large bay,—the tidal water fluctuates about twenty feet. Manchester is a manufacturing city, also; there is lots of trade there, and the sewage proposition is a very trying one, as it has been in most of the cities in England. A Commission was appointed; they rec-
250 ommended purification. Now, most of the engineers going to Europe have visited over at Manchester, the works are very large, but I do not think that any one feels that he would like to see a work of that kind in this country. I want to say, in defence of their efforts, that they did not have money enough to do all that they intended to do at the outset; because it is expensive; but, the interesting part to me is this: I knew —, —I won't mention his name,—I will say that he is a high authority in the same profession with me in Manchester. He said to me, in the year 1900, that "it was a great mistake that we did not build a big trunk sewer and go out to sea, to Liverpool, or down in the Mersey." "Liverpool is now discharging all of her sewage into the Mersey, and nobody knows where it goes. It is not visible." But he said to me: "Don't mention that to anybody; it might cause a lot of trouble" It is a personal opinion of his. I saw him again this Summer, and I reminded him of that. I said: "How do you think now?" He said: "Why, I am publicly advocating it; as the best method of disposing of the sewage of Manchester." Now, England is ahead in sewage purification work. It is a very nice thing in small ways, small towns,—it is a nice thing where you have large areas of sand like Berlin and Paris, and a terrible thing where you have not the sand or the areas. Because this was expensive, and you cannot generally get all the money you want to do things in England. It is a practical question.

This question must be divided into three: One is hygienic;
251 the other is that of nuisance; the third is that of cost. The cost controls in most cases.

In this case, I do not think the cost controls or should control, because this Metropolitan District wants the best, whatever the cost will be, provided it is reasonable, and, while I believe that the sewage disposal of the Passaic Valley by purification will cost more, I am not prepared to say exactly how much more, and I am perfectly willing to say "Let it go at the same cost" because we do not know all these things so well that we can prognosticate exactly what it is going to cost now—while sometimes we are right in an estimate of cost, sometimes we are very far wrong,—so let me say it is the same cost, because I do not think it influences this matter at all, but the hygienic question and the nuisance question, now these two, it seems to me, must decide this. Now, the hygienic question, I see, is approaching a very satisfactory solution, although we are not prepared to give any facts, and are not prepared to build any works yet,—and it is to add something to the sewage which will destroy the pathological bacteria and other bacteria which cause disease. If we can do that, we have destroyed the cause of disease in sewage, and there

is nothing more to be said about that thing. We do not drink this water. That, really has no value in potable water,—and where you put sewage is not potable water, and I may say here, unless I am taking too much of your time, that I do not believe it is proper, in a civilized community, in the largest city of the Western
252 hemisphere to raise oysters right here in the Bay even if we purify the sewage. I don't think the oysters fit to eat, with all the street wash of the City of New York going into the Bay, and which will deposit more than sewage deposits which is mostly oxydized through being exposed to the air; and, although, as I say, all the sewage of this district, New York City included, should be purified, I do not think that the oysters would be fit to eat on this account; therefore, I have never considered seriously the expressions on the oyster question here in this harbor, nor very much the fish question, for that matter.

Just one more thing. I will say that I am by no means of the opinion that you cannot purify sewage to-day. You can; we have done it; we are doing it today, and can do it very satisfactorily, and I can give you no better proof than this: Many years ago I was in Europe, as I am frequently, and I visited the Berlin farms and the Paris farms. I have seen them since, several times: I had my boy with me, eleven years old,—I drank the effluent from both those farms; so did my boy; he is now twenty-eight years old, strong and healthy. I never for a moment doubted that the sewage was purified, because I knew exactly what took place. We have now in this country, at Framingham, Massachusetts, a plant where the sewage is purified, the effluent is pure, but the operation of the work is not wholly satisfactory,—it is intermittent, and there is a nuisance discernible for a considerable radius, which no community in this Metropolitan District would sanction.

253 I believe, as an engineer, serving a community, that his recommendation should be that which is best for a reasonable sum of money, and which will, therefore, satisfy all demands.

About the nuisance question I have not quite finished. I think I spoke about that yesterday; that, in order to prevent nuisances, you simply have to have an isolation — sufficient isolation and dilution, and that removes the nuisance, so that if you can get that dilution, you prevent your nuisance. Now, gentlemen, I have heard it said, by some sanitarians: "You are all wrong when you talk about this dilution! You cannot dilute microbes: You want to get rid of them all. You don't want to put sewage into the sea water or into water with them in it, you want to get rid of them all before." If we could follow out the effluence when it leaves the sewer outfall, as we would like to,—and possibly with the aid of money, things will be different,—but I have viewed this question of dilution from a practical point-of-view,—not from theoretical point-of-view. It occur-ed to me: It is the same as this room. We are exhaling carbonic acid gas; we are exhaling, some of us, possibly, disease germs, yet we would not think of recommending some way of attaching a pipe to our mouths and purifying the air before it was discharged into the atmosphere. This air we are in has a certain capacity for removing certain refuse matter which takes care of this pollution to

an extent; we do not know quite how much, but we have
254 found, in fact, that the air settles, becomes heavy, under circumstances such as these, with a large number of persons breathing in a more or less limited space, and we open a window, or a door, and ventilate; we know about how much air is wanted per hour, and in the same way we know how much water is necessary for the proper dilution of sewage; there, also, oxidation is taking places the same as in the air only a little slower, so that I have thought, as it was necessary to get more air, to purify the atmosphere of the room, by adding ventiation, you are solving that question. So that I have thought it was the United States way of solving this question; and the water of our towns should be utilized for street washing to a proper extent, and no further. It means taking a certain amount of filth from the city,—the surface washings; we could not purify this,—the question is, how much solid matter is left in our sewage after going through the screens. Let us ask ourselves reasonable questions like that, and then we get our opinions and information concretely.

I do not know whether I did say anything about it, but I find that most of the black muck found, of which we have heard so much about down here in the Bay, is mineral matter or organic matter slowly decomposible and which is the washings of the unbounded surfaces of this community,—there is very little of it from sewage, which has mostly been destroyed by oxydation or consumed by marine life, before it reaches the harbor.

Col. Knight: You stated yesterday something with respect
255 to the amount of water with which the Chicago sewage should be diluted, and as I remember, you said something like three and one-third cubic feet of water per thousand of population, was that it? So much per second?

Mr. Hering: Yes, sir.

Col. Knight: Then that amount of lake water to each cubic foot of sewage: Now, what would be the proportion you would think necessary, between the different effect of salt water and fresh water, necessary here?

Mr. Hering: The Chicago dilution is now, when I saw it last, early this year, 2.65 (two and sixty-five one-hundredths) cubic feet per second per thousand persons who discharged sewage into it. So that, taking it roughly, that we require four cubic feet here,—I don't know why I fixed that figure just now, but it is almost double what it is in Chicago. I do not think it is necessary to have a greater volume than in Chicago, although it is salt water, but, conveniently, let us take four cubic feet,—the chief reason why, perhaps, I might give that figure was is that New York has polluted this water already to some extent, although perhaps in different currents, along different lines of water from what those are where the Passaic Valley Sewerage Commission proposes to have the sewer discharge. And then, too, perhaps, we might also say that the decomposition is slower in salt water than it is in fresh water; so that if we take four cubic feet of this bay water per thousand per second, for one million six hundred thousand persons, which is the population provided for,

we would have six million four hundred thousand cubic feet
256 per second required to dilute the entire Passaic Valley sewage in the proportion of four cubic feet per second per thousand people, that is, six million, four hundred thousand cubic feet per second. Now, suppose the average velocity of the salt water at the worst time, that is, when the tides change, when the water seems to stand still—of course, it does not stand still for a moment, at least at certain parts of the harbor, but let us suppose the average velocity of three inches per second,—I want to say it does not stop that way, but, for argument, let us assume these three inches velocity per second, moving up or down,—(there is an under-run which continues after the tide has changed on top, and various conditions govern, differing for the water at various depths, and if you take the water altogether, in a vertical section, it is moving in the section somewhere). Now, take the average velocity at the worst time, of three inches per second, where there is the very slightest movement,—that is, we would require a cross-section of twenty-five thousand six hundred square feet. Now, as the average depth of the shaft is going to be about forty-five feet or thereabouts, that is, we require a width of discharge area of seventy by five hundred and seventy feet (Now those are only just assumptions as I have made and are of course, rudimentary,—my original figures at the moment). Now, if the velocity is six inches per second, and I am pretty well convinced that that is nearer right than three inches per second, for a few thousand feet—or for half
that distance of five hundred and seventy feet, or two hundred
257 and eighty-five feet, which is the half of the width of the dispersion area, this sewage is to be dispersed then in a current two hundred and eighty-five feet wide and forty-five feet deep as it passes from those openings and takes this sewage from perhaps several hundred openings (And I don't know how you can compare a dispersion which takes place all over the bottom in this way, with that which follows at Boston from a discharge practically at the surface, out of a pipe which runs upward, while the dispersion here is horizontally and down the slope),—then you would have somewhat the conditions as in Chicago—you would not see it anywhere, in Chicago you do not,—I mean on the surface.

Col. Knight: You leave it to the Board—you refer to leaving it to the Board to determine the amount—the size of the sedimentation basin; do you mean,—shall we infer at all from that that you do not deem a sedimentation basin necessary yourself?

Mr. Hering: No; I certainly would recommend a sedimentation basin if for no other reason than this fact, that Newark and Paterson have not the separate system and there will be a great deal of storm water and street wash going into the sewer from their combined system and that ought to be taken out. Now, after the separate system is built over the whole area, then, it seems to me, the necessity for a settling basin would largely diminish, but I am really not prepared to say now as to what I should recommend under
those circumstances, but I certainly would recommend one
258 now because of the silt that Paterson and Newark would unquestionably bring into the sewer.

Col. Knight: But you are not prepared, at this stage, to pass upon any dimensions?

Mr. Hering: No, sir; they have not been computed. We never made any assumption.

The point I would like to have settled, if I had the opportunity, is what will be, what will have to be the size of the particles that will continue to float along up the moving water of the Bay without the tendency to deposit. Of course we all know that there is a fixed relation between the weight of the particle and the velocity of the water which will keep it in suspension. Now, if course the velocity gets less sometimes, then stops then goes the other way, and very probably most of the depositing takes place at the time of least velocity; therefore, it is very likely that this is a question of adjustment more than anything else; as to what size should we want, or permit, to go out into the bay, and, when that size is determined,—or the weight I should say perhaps, not size—then we can say—we will come to know to say it is not going to deposit, or we will have a deposit of so much, when we have the velocity fixed at so much per second, it is a matter of pure arithmetics to compute, and as to the design,—what would be most agreeable to the Commission would be for you to estimate the velocity of the water in that basin, because that would enable us to compute the size of the basin; because it is difficult now to say just what size of particles will be permitted to go through so as not to occasion a deposit.

Col. Knight: Well, now, will not your screens take care of that instead of the settling basin?

Mr. Hering: No, sir; the screens take out the large floating matter.

Col. Knight: But you were speaking of screens of a millimeter opening; will large street refuse go through that?

Mr. Hering: No; well,—perhaps seventy-five per cent. might go through,—all of the very fine matter, and the most of it is the fine matter, will go through. These millimeter screens will only take out twenty-five per cent. at the most. Now, what is left? Seventy-five per cent. That goes through, and it is so fine that you must realize that it will float to a large extent,—and there is the difficulty about suggesting just exactly where you want to draw the line in that prime matter. Of course, coarse screens should be put up to keep out the coarse matter, that which would otherwise float on the top of the water and be objectionable in appearance, but the usual screens employed in the foreign sewers range from a half inch—from a half-centimeter to an inch,—and I would say that in my opinion anything less than five millimeters might cause trouble and should not keep out more sewage. And, it is a remarkable thing,—which we do not quite understand yet, unless you consider that seventy-five per cent. is very fine, in this proportion it is very fine particles of matter; of course, the chemists determine this by evaporation and other processes, and determine that this seventy-five per cent. does go out through the finest screens.

Col. Knight: But you do not say anything which helps towards

arriving at present at what should be the dimensions of the sedimentation chamber?

Mr. Hering: No, sir; not yet. I do not think we have any evidence on that subject. We have not tried to get it, because there has not been any money to do it.

Col. Knight: But you think, with money, it can be determined?

Mr. Hering: Yes, sir; I think a reasonable result can be determined.

Col. Knight: Then, would it not be a fair restriction on this permit, if issued, to require that that should be determined before the permit shall issue, being an essential part of the proposition?

Mr. Hering: I would not like to answer that question in the presence of the members of the Commission. That is a matter of judgment. I think that—as my personal opinion, as the opinion of an engineer—I would say that I should not have any hesitancy in fixing a certain amount, a certain size of settling basin, but I would admit that some might object to it, and have good grounds for so doing.

Col. Knight: You consider that it would depend on the velocity of the sewage as it passes through the basin as to how much is deposited there?

Mr. Hering: That is a very small matter—a very simple
261 matter, to make the settling basin larger or smaller; this can be determined in easy fashion after the work commences, as the settling basin and its dimensions can be determined later, one of the latest things to be built; that is a question that perhaps might be solved after these works have been perhaps half or three-fourths constructed; I should say that it might take a long time to settle that question to everybody's satisfaction; but I personally should not hesitate to go ahead and build it, and I would build it, and I would think I was doing my duty because I would believe in my work,—the results of all I have seen in Europe would go into the work, and we make those points the subject of enormous study, the most constructive points that there are I have usually tried to see. It is merely and simply a matter of judgment, not calculation or scientific certainty.

Col. Knight: But there are in certain sewage systems—you were speaking of the character of sewage at Hamburg: Do they use screens and sedimentation basins there?

Mr. Hering: They use a sedimentation basin which, if I remember rightly, is about the size of this room, and screens one inch apart——

Col. Knight: But they do use sedimentation basins?

Mr. Hering: Yes, sir; to that extent, and, let me say this,—that it is only for very large matter; the velocity of the water going
262 through that sedimentation basin is doubtless a meter a second,—between three and four feet a second; now you are not going to get any very fine deposit at that velocity,—only very large matter drops down there. By screening, the large floating matter is prevented from going out,—by sedimentation——

Col. Knight: All the sediment is screened——

Mr. Hering: The screens are located over the sedimentation basin——

Col. Knight: And it is only the matter that is caught by the screens that goes into the sedimentation chamber?

Mr. Hering: All of the floating matter is caught by the screens——

Col. Knight: But all this matter that drops as a result of the passage through the sedimentation basin would be caught on the screens?

Mr. Hering: Possibly it would; only it is far better to have it separated, so that it can be dredged out properly. At Hamburg the screens move, and whatever of the soft floating matter lodges against the screens is removed; the screen is lifted up and travels along and is then scraped off at the output into a moving trough, and that moving trough is emptied—it empties this stuff into a canal boat lying constantly alongside, then taken away; there is supposed to be a canal boat alongside all of the time. But let us suppose that a stone or a log is going through the flow into this screen chamber, you could not pick that up on the screen; therefore, there is a sedimentation basin there to hold that.

263 We have a dredge running there—opposite the works——

Col. Knight: Then there is a deposit as a result of this sewage outfall at Hamburg?

Mr. Hering: There is a channel there,—the big Hamburg-American line boats pass right over the outlet; whether the dredging is made necessary entirely by this outfall it remains to be seen; the fact is that there is a dredge running there practically all of the time, but the system of dispersion there differs entirely and is governed by different conditions of current and dilution.

Mr. Kissam: Mr. Hering, do you think there would be enough water at a point in Newark Bay, say, near the Bergen Point Light, approximately near where the Arthur Kill and the Kill van Kull and Newark Bay join,—do you think there would be enough water—water sufficient to cause the necessary oxygenation of sewage discharged in or about that point, provided the sewerage was screened and sedimented about as proposed?

Mr. Hering: That has been recommended to me, but was not considered by me.

Mr. Kissam: Well, what is the objection to it?

Mr. Hering: There is no other objection to it than that it is only a question of time when we would have to bring it out to the Bay—a question of time when we would have to bring that up. Now, in this proposition, just what composition is discharged into the middle of the Bay is significant, and is as recommended, but there you can get a discharge at the bottom of the Bay, and I think you

364 cannot get a discharge into the bottom of the Narrows, but I think the dilution would be sufficient to render it in-occuous, at the points referred to.

Mr. Kissam: And that still remains true after twenty-five years?

Mr. Hering: No.

Mr. Kissam: Well, how long, in your judgment, would it remain?

Mr. Hering: That is very difficult; I have in my office——

Mr. Kissam: Well, how long do you think?

Mr. Hering: I have calculations on that subject. I know it has been gone through——

Mr. Kissam: You did consider it?

Mr. Hering: Yes, sir; it is only a question of a few years, and then you will have to go somewhere else, which necessarily involves the loss of money and time. I would like to say, in passing, if you will permit me, that the future of these matters is a factor that should never be lost sight of by an engineer advising the investment of many millions of dollars. I do not think that this sewer is the end of things. There is going to come a time when something else will have to be done with that sewage just as with the New York sewage. Where can you do anything in this great Metropolitan District? There is only one place, and that is below the Narrows somewhere.

Mr. Kissam: Well, is not the alternative remedy the sprinkler system you suggested——

265 Mr. Hering: I am not prepared to say what should be done with the New York sewage——

Mr. Kissam: I mean the City of Newark——

Mr. Hering: The alternate is a sprinkler system; yes, sir.

Mr. Kissam: That would be entirely feasible?

Mr. Hering: Yes, sir; from an engineering point of view.

Mr. Kissam: What would be the objection to that?

Mr. Hering: The objection would be this, in my opinion,—not as an engineer. You have to have a considerable area around this plant to protect the outside from the odors coming from it, because the sprinkler system causes considerable odor. Now, I am not so certain but the time will come when we will house some of the sprinkling filters; we have housed some of large dimensions that way. You will have to have about one hundred acres for this sprinkler-filter,—something like that. You want to have plenty of land around it, to prevent the odor from becoming offensive, and I think that half the section lying below the Hackensack, or something, I forgot the name, would have to be devoted to it. Well, now, that part of Newark and Hackensack Meadows is, I believe, going to be built up and populated as soon as some method has been found to fill it or to drain it and get it ready to produce something and return some revenue for its position—it has a very very attractive position for many purposes, right between Newark and New

266 York, and this sewage disposal system would be a detriment to the development of that whole area, and is so considered in Europe. It is not a place where you go with preference,—you go away from them with preference, although I admit that there are places along these sewage disposal grounds where people live, but you find them nearly always alone, in intermediate districts where there are no conveyances, or practically none, and I do not know of any of these larger processes for purifying sewage where people live up close.

Mr. Kissam: Have you considered the Newark Meadows at or near Elizabeth?

Mr. Hering: That is just where—that is the locality I was referring to——

Mr. Kissam: You said Newark——

Mr. Hering: Well, that is just where such a plant would have to be located——

Mr. Kissam: Have you gone over that territory?

Mr. Hering: Yes, sir.

Mr. Kissam: It has no buildings? Is barren land?

Mr. Hering: Yes, sir.

Mr. Kissam: It is an absolutely barren territory, is it not?

Mr. Hering: Yes, sir.

Mr. Kissam: Ranging for miles from the Bayonne peninsula, off for several miles?

Mr. Hering: Yes, sir.

267 Mr. Kissam: Now, the point I wish to make is this: I represent the City of Orange, and, of course, the element of expense is very important to us; the cost of that deep tunnel sewer will be about twelve millions of dollars, and the cost to us will be about six million dollars, or about one-half of the whole estimated cost of the entire project. Now, the point I make is that there is no necessity for the granting of this application, because it is entirely feasible to put in a sprinkler system on the Newark Meadows which can entirely take care of this situation, the only objection to that, is the odor, and the possibility of being a detriment to the building up of those meadows in the future.

Now, we do not, in the City of Orange, object to improvements; we stand prepared to do everything we can to clear the Passaic and make the Passaic River a beautiful strea-, once more, but we do not want to be put in the position that where these Commissioners have wasted a large amount of our money, to be compelled in the course of a year's time or in the course of a few years, in the course of a generation, or fifteen or twenty years, to pay this thing all over again, because then it would be necessary to establish a sprinkler system because of the condition of New York harbor. If New York harbor is to become so vile, in the course of a reasonable time, that it will cause disease, be offensive, become filled up, and the people will have to stop sewage into New York harbor, it seems to me very unfair to us to tap the smaller towns to a point where it means almost absolute
268 penury in order to experiment with this sewerage disposition system into deep water, which is entirely unnecessary,—I mean when they admit that the sprinkler system is entirely feasible. The point I make is that it is not necessary because it is possible to dispose of all this question by erecting the sprinkler plant.

Dr. Brush: The hour is late, and I do not wish to detain you, but, speaking for the Booklyn League, which is composed of over a thousand of our business and professional gentlemen of Brooklyn, I appear to oppose this proposition for the reason that the added pollution of this proposed sewer to the waters of this Bay will simply add to the difficulties which have now been demonstrated by the examina-

tions of the Merchants' Association which, I suppose, are before you,—if they are not they will be, in a pamphlet which shows that pollution by sewage in the waters of New York Bay, and while the waters are not potable or drinkable as with Boston, at the same time there are matters deposited that are along the surface, and that is a question that has not been spoken of at all here to-day, or at all so far as I know—I unfortunately could not stay yesterday and lost a good deal of that which has been said, and if it has not been said, I want to say it,—we know that they have demonstrated that the intestinal diseases during the period of floods are very largely increased in the localities where this deposit is upon the posts and piers of the wharves of this City, and they have traced it to this: flies
269 alighting upon the posts and then upon other materials and thence taken into the stomachs of children and adults as well.

Now, we protest against the pollution of the waters of this Bay any further, with any other materials that has not the bacteria destroyed,—any pollution, and it seems to me that in view of what science has revealed to us in the twentieth century, in view of that, it would be a shame and a disgrace to empty into the waters of New York Bay six hundred thousand gallons or six thousand gallons in which the bacteria of typhoid germs, germs of tuberculosis and all of the forms of disease that we know are infectious and perhaps contagious and especially infectious are contained.

And that is the ground upon which we base our opposition. It is on humanitarian grounds; it is not a question of taste and sentiment; it is not a question of smell; it is not a question of what we can see. Our worst enemies you cannot smell or see; these germs are hidden, and they attack us in points where we least expect it, and, therefore, I say that we should not consider for a moment the granting of a request which will enable any one whether in New York State or in the State of New Jeresey, to pour more pollution into the waters of this Bay. We are trying now, and have been trying for the last year or two to get legislation at Albany which will prevent any further emptying of sewage into the waters of this Bay, and we are studying that question with a view to trying to get disposal plants which will obviate the necessity for that, which will
270 make it necessary for the City of New York in the future to entirely re-construct or re-arrange her sewage system—and it certainly ought to be done in the interests of all; and, therefore, I am here to say that we oppose the granting of this permit.

The Chairman: The hour of half-past one having arrived, a recess will be taken until two o'clock.

(After Recess.)

The Chairman: Gentlemen, if you will come to order, this hearing will be resumed. The Board is prepared to hear anything further on the subject.

Mr. Harrison: There has been a considerable discussion here, and a number of statements made that may lead the Board to believe that the proper thing to be done in this Metropolitan District is to

undertake the construction of a sewage disposal plant. That would mean, I presume, in the opinion of the gentlemen making this statement, of the whole Metropolitan District in and about the City of New York; that we were to commence to establish a plant to take care of all this sewage in a sewage disposal plant, and, when I say the whole Metropolitan District, I would mean the whole five or six million people who now drain into the harbor of New York. That statement is a most extreme one. I know there are engineers in the profession who believe that all sewage should be passed through treatment and the effluence should be more or less pure. Some even go as far as to say that the effluent should be fixed so that it could be used as drinking water,—and they are very like some doc-
271 tors. I know doctors who say that the proper thing to do with a child is to remove his appendix, that it is a bad thing to have and it is better to have it removed at once, rather than after it may have caused trouble later on in life.

The way the great conservative body of engineers who have studied the sewage question think, and I am one of those, and I think the great body of conservative men look at it, and I believe the officials of the City of New York look at it, is this way: that the way of New York, the Hudson river, and the great balance of the topographical features of this Community, this territory here, the East River, and so on, where the large amount of tidal inflow through it and the periodically large, enormous flow down the river means the best relief for the City of New York and for this community. Now I wonder if it is realized that in order to provide a sewage disposal plant and the necessary modifications in sewers, etc., it would require a capitalization of two hundred and fifty million dollars, to complete it, for the City of New York alone, would require the investment of two hundred and fifty million dollars. The gentlemen here representing the different boards here, and representing the different parts of the City of New York can represent whether the City of New York is prepared for some years to go into this thing, from a financial standpoint, and, when you do this, you cut yourselves loose from the natural advantages which have been yours and would be yours for all time. We think that it is proved by the evidence submitted to the Governor,
272 and to the City of New York by the Pollution Commission, and also can be proved by their statements that at the present time the great body of water in the harbor of New York—of which we claim to be a part—which we are—we claim to be a part of it,—of this Metropolitan District naturally draining into the harbor,—that the great body of water in the harbor of New York is practically unpolluted. When I say unpolluted, I mean it is not fit for drinking water,—it is not potable, but I mean that the quality of the water is practically standard,—of the standard accepted all over the world for great commercial harbors,—practically unpolluted.

I do not think that any of this Board, gentlemen, can find any harbor in the world—with a community as large as this draining into it, with water that is as pure, as clean, as the water of the harbor

of New York. You won't find it in London, Rotterdam, Amsterdam, Genoa, Venice, or any of the great commercial cities.

Now, generally, I believe that all of these cases should be treated by themselves,—these cases of sewage disposal. We believe that inland developments, such as the city of Columbus, Ohio, and a number of Pennsylvania towns, and inland towns and localities in general, where the surface sewage has to be gotten rid of by some means so that the water is not carried into a stream thereafter to be used for drinking purposes,—that some method should be taken to treat it. But, we believe that the system—that where a community has a great purifying element right at its doors, that
273 natural right of having a large body of water, capable of diluting the sewage of a community and rendering it inoccuous, have the right to use a proper, economical method of sewage disposal, and I think that is the idea of all engineers who are not specialists in some peculiar line.

Now, there is no doubt in the minds of this Commission, nor in the minds of any of those engineers who have studied this subject, that the harbor of New York, with the water we have got here, will take care of the needs of from twenty upwards millions more people,—of the sewage of those people, more than at present drain into it, and the New York Bay Pollution Commission nor anybody else ever said anything to the contrary. They all agree that at some indeterminate time ahead New York will reach a point where you will have to look out for the harbor, but that time will not come until the population draining into the harbor will have reached at least twenty million, and, of course, when I say that it will care for the sewage of twenty million, I mean if it is properly distributed so that the sewage is not locked up in estuaries and stacked up in the slips and piers, but goes into the harbor freely distributed. And this same condition of affairs has been considered.

Take the Boston case, which we hope to improve upon: In Boston, the sewage comes out of the sewers at the end of a pipe, a large pipe, in one mass. Now, the rapidity with which that sewage is oxydized, and the offensive characteristics taken care of, depends upon the quickness of dispersal, as the air cannot reach the solid
274 column of sewage discharging at the single outlet; that condition is one which we propose to change practically by means of our plans for dispersion of the sewage at the outfall. The same as when you put a lump of sugar into water; the lump dissolves slowly, and remains in the water a considerable time, but if you put the same quantity of sugar in the form of powdered sugar, into the water, it is gone quickly. That is our principle for our work.

Now, we come to the disposal works. As I say, where things are such that it is impossible to get an outlet, those towns labor under that disadvantage: Why should they wish to put this great community to that disadvantage, when they have the water here, and there is no question about it, nobody claims or has ever complained of the existence of a nuisance in the waters of New York; and these gentlemen have often, no doubt, noticed the presence of a nuisance

alongside the ferry slips, at low water,—which I have seen at Courtlandt Street, and at 34th Street, and at 42nd Street, and, especially there alongside the gas houses; we all know that Newtown Creek is another Passaic; and it is no wonder, with the sewer system in vogue; that is the point we want to reach—this sewage should not be brought into the pierheads, but should be so discharged into the tidal waters as to mix it and disperse it with the enormous quantity of water we have got here. In Boston they have done it, and we improve, in our proposition, upon the Boston methods, and I do not understand at the Boston works that they propose to give it up.

275 Here we have the State of Massachusetts, which has made more advancement in the methods of sewage disposal work than any in the world—in this country at least, and they have gone into extensive experiments above all others, and yet they adopted this plan of general ocean disposal,—they are extending that plant,—not thinking of giving it up.

You have the City of Baltimore with a disposal plant. Why? Because the lifeblood of the City of Baltimore was in Chesapeake Bay and the oyster beds and fields; they believed, and they were afraid that if they disposed of sewage in the Chesapeake Bay, and there should be a general knowledge of it, possibly that business would be ruined. That don't apply here. The gentleman talked about the oyster fields on the Jersey shore; well, I have lived around in this community, on the Jersey shores, for forty years, and we have cultivated other things than oysters on the Jersey shores.

Another of the points I have to speak about. I do not know, and I do not believe anybody knows of a sewage disposal plant anywhere that is absolutely satisfactory. We have gone into it quite extensively in New Jersey in some of the suburban towns. We started rather early in it. The town of East Orange started in over twenty years ago, and the engineer who put in that plant for East Orange wrote a very able paper on the subject after it was finished, and it was quoted as a very lucid statement of the case, giving a very great deal of enlightenment on the subject of sewage

276 disposal, and it was generally believed to be a successful plant. Recently, in conversation with a resident of that city, he said they were going to give it up; that he has not seen it in years——

Mr. Child: It has been abandoned.

Mr. Harrison: So there, you may believe, they have very little faith in sewage disposal plants of whatever kind. This is particularly true with regard to the system of disposal that was adopted for the town of Summit. I lived in Summit for two or three Summers, while the plant was working, and whenever the wind was in the right direction, the whole of Summit knew that they had a sewage disposal plant, and whenever the wind was in the other direction, the neighboring towns had the same knowledge forced on them. I am consulting engineer to the East Jersey Water Company, the corporation which supplies Jersey City with water, and I know that several times we have had to notify Summit that—

although their plant was twenty-five miles up the river,—the raw sewage was coming down to the pump works at our plant.

I had occasion, not long ago, to look into the plant at Richfield, and there they have a plant on a gigantic scale, complete in all respects, a plant built by engineers who stand pretty high in State of New Jersey and the City of New York, and at this plant they had put in contact beds and septic tanks, and then ran the effluent into a creek through a concrete channel, and if you will go up there to-day you will find the channel all cut up, the chan-
277 nel stone piled up on one side, and the raw sewage running through on one side into the creek; the concrete beds did not work as they should.

I heard a little while ago, when I looked into the broad irrigation plants of Westfield, the water worked its way over a portion of Westfield, and to take care of that they went over where there was more territory; that plant, as you will admit, is a well-built plant, but that plant should be at the effluence, which we would have no objection to, putting the effluent into reservoirs, it was found that the effluence did contain an odor, which might have been anticipated, but we did not expect to find at a distance of two and a half miles from the effluence, actual effluent from that sewage plant discharging into the Rahway river at tide water.

Now, there are also several plants at institutions, I should say,—at Morris Plains, at the Normal School, and at small institutions; there you probably have a million gallons or less than a million gallons; those plants work; that is, they do very well, but when you come to figure up the cost,—they are all in the hands of skilled men, who take care of the institutions, stay there, live there on the place, and always watch carefully about the cost, yet the cost per million is prohibitory, when you have several million gallons a day, the cost becomes practically prohibitory, and when I say prohibitory, I mean reasonably prohibitory. It may cost the City of New York a great deal to take care of its sewage under such a system,
278 but that would not mean so much to so thickly populated a community, the same being true of Newark, but when you get up into the State, to the towns and cities right up on the Delaware, where they have to use the water for drinking purposes, and must dispose of the sewage, many of them cannot afford to go to that expense.

Moreover, abroad, you find disposal plants all over England, and I have never been near one yet, never been around one of those disposal plants in Summer but what you can tell there is a disposal plant there. Those plants always send up that sweetish-sour smell of sewage, at all times during the Summer. And we get knowledge of them the same way in the continental plants. The gentleman who spoke of the Berlin plant the other day said that it does not smell there; that may be the case, but it is a fact that nobody lives there.

Then, another thing, the effluents from these plants are not what these gentlemen think they are. They are not fit to drink. They simply look pure, and are very apt to contain a portion of the sew-

age, and do as a usual thing, they are entirely clear, it is true, but not fit to drink.

One thing you want to remember, and a very important point in this case, I think, and which I forgot to mention here in my discussion yesterday, and it is, when you take the sewage out of the Passaic River and out of Newark Bay that will give you about one-
eighth of the flow of the Bay—the flow of the Narrows, in
279 pure water. At the present time the waters of Newark Bay and the Passaic River are almost totally devoid of oxygen, and have not any in Summer, but when we take those waters running through the Narrows into Newark Bay, you abstract a portion of the oxygen which is in the Bay; but when we take the sewage out, you will have one-eighth of the ebb flow,—the flow of the Hackensack is about one-eighth of the Narrows flow, you will find one-eighth of the Narrows flow coming in there with practically pure water, with plenty of oxygen in it, ready to help to reinforce the oxygen of New York Bay and thus oxydizing the sewage as it goes into the Bay.

Now, I think, and our point is that though at first blush it seems to be quite a proposition to ask permission to do what we are asking to do, yet, any New Yorker, who thinks over the subject and comes to understand it, will ask himself why they should be at present opposed to this plant? We will take the sewage out of the Bay, and clean it for you, and in doing that, we are taking from New York a right worth two or three hundred million dollars, and now it may be said that when the population of New York or of this Metropolitan District draining into the Bay shall reach twenty millions in all this section, you will have to take care of it, but what engineer here will be fool enough to say what methods there will be for the disposal of sewage at the time when the population of this section reaches twenty millions. We may be turning sewage into whiskey or alcohol then.

Another thing, how do we know that there will be a poula-
280 tion of twenty million in one congested mass? If this is to be a city of twenty million population, just try to imagine what the effect will be of four times the population in the crowded streets of New York; how would you supply them with food, where would you get the railroads to serve them? All of these things must be considered. So, it is doubtful, a very doubtful thing, and no one credits this opinion as to what New York is going to be in twenty years. We all know, and you gentlemen know, that in 1866, a gentleman then at the head of your Health Department, wrote a report in which he said that New York harbor was filling up, and he asked that a report be made after a survey of the conditions; and the result of that report was—the gentleman believed it was filling with sewage,—he thought that sewage was having a great deal to do with it, but the fact was that the report showed that a number of individual contractors who were dredging in the harbor, who dredged around New York, were dumping their dredgings on the Jersey flats; they dumped it on the Flats without any bulkheads; that dredging was running down towards the channel, and a survey was made which showed along the Jersey Flats dark lines sixteen to twenty-

five feet below high water at the large channel, for about two hundred feet, and of course in the Flats it don't take very much filling to bring in two hundred feet. Then there was a great time made about it, everybody said that the harbor was filling up, particularly this Health Commissioner, and he said they would not be able to get the Great Eastern in,—the "Great Eastern" was the big
281 boat of those days. The report was made out and a regulation made, which is that regulation which applies to-day, that no more filling should be put in except inside of bulkheads; the regulation being enforced, there was a large improvement as after that all this filling was stopped. Now, this brings us to the question of deposit. I have a very intimate connection with the bottom of New York Bay, especially on the Jersey side. I made the first investigation for the present Pennsylvania improvement,—the borings and soundings. I have made very numerous investigations since then for railroads with regard to terminal facilities; I am very familiar with the depths of water, and have been familiar for the last thirty years, during the time that New York has been growing from a population of five hundred thousand to four million and up, and am acquainted with the theories of this flowing mud and its deposit, having made soundings and done general contracting work on the Jersey shores, and I do not think that there is any change in the amount of deposit, one way or another. If you will examine the Coast Survey Report of 1865 and their charts, you will find that to be so except where artificially filled in. Whenever I have had occasion to examine the bottom, this has been my experience, and on an occasion where I examined I found the river four feet deeper, that is, from Jones street North, from our dock, North. I believe the channel is about that much deeper, or more. Of course, that would be natural as a result of bringing in the bulkhead lines.
282 I have consulted with engineers on this point, and they are agreed. I do not believe, with the sewerage in New York Bay, you can change the arrangement of the Hudson River or New York Bay by the deposit of sewage; the river will take care of this. I also took this point into consideration: That the enormous flow of the torrent of the Hudson in the Spring, as you and I have seen it running ebb away down below the Central Railroad Bridge, running full of silt and mud and muck the result of the Winter's accumulation in the ice-bound waters from the whole of New York, which makes a deposit when it goes out beyond the Bay, after being brought down through the gorge of the river, and this may likely leave a deposit in a manner practically as it flows, just as has been going on in that locality for many years.

Now I understand what has been said—and I do not want to let it be understood that the engineers of this Commission do not deprecate the conditions of articial disposition of sewage, as to conclusions from cost or taste. One of the most important factors entering into this matter is as to the business side, the side of commerce, the economical, proper sanitary welfare of the public and, taking everything into consideration the engineers of this Commission have concluded that the proposition involving the least risk, is the allowing of that sewage to pass into the water, under the conditions outlined. Now,

there is one point,—they seem to have an idea here that we are relying entirely on currents. Now, we do not. If you put one
283 part of sewage into fifty parts of ordinarily clear and pure water, water with the natural amount of oxygen in it, whether salt or fresh water, and fresh sewage, the sewage so put in is inoccuous, in salt water in a tank, in sea water, or in anything else. That point is of importance to us; of necessity,—the currents of usefulness,—the presence of the currents is advantageous as it involves the presence of a large body of fresh water and of clean water, and we can arrange our sewage for passing through it. As Mr. Hering told you it is our purpose to have the sewage go out slowly; we can regulate it as it goes through our works. Boston cannot. Boston sends it out by gravity alone, without control. With us, in our sustem, it is only a matter of a little more coal to get a greater head on, or a little less coal and a slower head. That is arranged by the pumps. We let it go out as we want it to go, and we mix it or carry it in the diluting water. Now, when you get one part of that sewage into fifty parts of New York water, it don't go five hundred feet away before it is imperceptible, totally passed out of sight and dispersed. In all the investigations made by Great Britain of the sludge from the London sewers as deposited in the River Thames; they take their sludge in large boatloads, take it down the estuary of the Thames to tide—deep water; when it is down twenty miles, they again throw it overboard, steam around in the same place, opening gates in the lower part of the boat, and allow the sludge to drop out. In ten to fifteen minutes, or in a very short time after that sludge is dropped
284 it is impossible to detect that any sludge has been put into the water, so far as the closest bacteriological and chemical tests can determine; it is gone. They steam around; maybe let the boat go down the river and special tests show that it has been taken up by the oxygen in the water, by the bacteria,—taken up by the small animalculæ around there; and there are a great many around there, it is a great place for fishing, any number of people always fishing around in that locality. That is what we think is the case here with our proposition in New York Bay, and we think that will last until fifteen or twenty million people populate this district, and then, by that time, the engineers, I think will take care of it, and it is ridicuous folly for the engineers of today to say what they are going to do with New York sewage twenty years from now. You might as well have asked the engineers the plans of the Hudson tunnel thirty years ago; they never would have been able to build it according to those plans,—and in fact they could not do it with the plans then made for that tunnel; and when I talk about plans of thirty years ago, for that work, I am talking from experience, as I have been closely connected with the railroads and with terminal matters of the Pennsylvania Railroad, and with the terminal affairs of other railroads, for the last thirty years, and when I first took those matters up, we thought that it was foolish to undertake to build the tunnel, we thought that there would never be a time when the needs of the country would require it; nobody ever thought of

dredging to a depth of thirty feet in the lower Bay, and
285 equally unthought of was the building of such a structure as the Pennsylvania Railroad is building today, and which is absolutely necessary for terminal facilities. I then made a report on the subject, and when it was put in, was practically concurred in by all of the Pennsylvania Railroad engineers; it was folly, we thought, to think that they would ever have such a railroad terminal. Then, I may say, in those days in considering dredging matters, we figured on forty or fifty cents a yard for dredging, and as high as Two dollars a cubic yard for filling; and now, with the improvements in mechanism for this work you know how the methods and costs have been modified: We dredge now for ten cents a cubic yard, and we get all the fill in we want for twenty cents a cubic yard; so that work which would then have cost upwards of twenty thousand dollars is now easily done for Five thousand dollars.

And, so I say, when these gentlemen talk about the waters of the harbor becoming a nuisance, or becoming clogged up, if we will measure the waters of New York Bay in the light of this big project that has been undertaken by the Pennsylvania Railroad, with reference to what was thought would be the case, and if we look at this matter on a large, broad scale, there is no reason why the great advantages of New York should be, or be attempted to be, changed from what we have learned they are, and it would really be a great mistake in a great community like this, where the first question is: Can you dispose of sewage by mixing it with water? Can you arrange its dispersion so as not to create a nuisance? and,
286 secondly, If you can, don't think of anything else.

Dr. Soper: Representing the Metropolitan Sewerage Commission, I read a statement yesterday in which the opinion of the Metropolitan Sewerage Commission was expressed, opposed to the Passaic Valley project.

After listening to all of the statements that have been made since then, I do not think that I should want to change the wording of that statement. It represents, of course, not my own views, but those of the five members of the Metropolitan Commission, all of whom have given this subject considerable study.

At the same time, in the proceedings which followed my remarks, my name has been mentioned several times, and some of the statements that I made have been criticized. For one thing, the name of Mr. Allen Hazen has been brought into this discussion as having contributed to the discussion of a paper which I read before the Sanitary reception of the Boston Society of Civil Engineers.

I should like to have Mr. Hazen's complete discussion before you, and, if possible, the discussions of Mr. Harry Clark, Chemist of the Massachusetts State Board of Health, and Mr. Coney, the Engineer of the Massachusetts State Board of Health. Mr. Hazen's remarks, if I remember them—I have not seen the discussion of the paper now for some time, referred to the inadequacy of the data upon which he based his discussion, and recommended that the studies

which were being discussed be made very much more full
287 and complete; those studies are now being made much more full and complete. The Metropolitan Commission exists for that purpose.

Mr. Harry Clark's discussion, if I remember it correctly, shows the danger of polluting tidal estuaries in the direction of injuring the purity of oysters and shell-fish. That point has been referred to here, in these statements that have been made before your Board.

Briefly: It may be unnecessary for me to extend them. It has not been brought out, however, that, within the limits of New York City, there are annually produced upwards of five hundred thousand bushels of oysters. They are marketed here and are eaten, for the most part, without cooking. Cases of typhoid fever have been accounted for, just as reliably, I think, as typhoid can well be traced, to the eating of some of those oysters; oysters cultivated and grown in the waters of New York. According to the latest statistics that I have been able to collect, there are grown annually about seventy thousand bushels (?) seven (?)* thousand bushels of oysters in upper New York Bay. This used to be a famous oyster-producing ground.

Mr. Hazen's discussion of my paper before the Boston Society of Civil Engineers, in common with the opinions of many other engineers with respect to the diluting-power of the waters of New York harbor for sewage, were based upon the assumption that all of the water of the harbor was available for diluting and assimilating
the sewage, and, apparently, upon the assumption that that
288 water was immediately available for diluting and assimilating the sewage.

It has been demonstrated, and fragments of the evidence have been put before your Board, that sewage discharged into the waters of New York harbor does not immediately become dispersed. It has been stated that the sewage floats about upon the surface to a very considerable extent. We should, then, consider, not the tidal volume of water,—not the total volume of water which lies there in the basin of the harbor and floats in and out,—the quantity which floats in and out with the tide when the tidal prism does, as available water for diluting and assimilating sewage, but its surface area, multiplied by the certain depth—the exact depth we do not know as yet—which is all of that volume of water so available.

One of the most difficult problems which we are studying to-day in the Metropolitan Sewerage Commission, is how sewage discharged into these waters can be so dispersed as to become inoffensive before it is distributed.

With regard to this matter I would invite the consideration of your Board to a report of the State Board of Health of Massachusetts upon the discharge of sewage into Boston harbor, dated 1900. You will find there evidence in the form of an official report, and a map, to which I would especially invite your attention—considerable evidence upon the effects of the outfalls of the Boston drainage, and

*(Stenographer: Probably seven.)

modern drainage system—also some facts, one of which I will briefly read:

289 (Reading.)

"At the outlet in our Deer Island Beacon, which is four and two-thirds miles from Long Wharf in Boston, in the windfall East of the main ship channel, sewage from the North Metropolitan District is allowed to discharge as it comes, in all stages of the tide. The quantity of sewage discharged in twenty-four hours now reaches about fifty million gallons, and this quantity, while distinctly visible along the Northerly edge of the channel for a half mile towards the City, on the incoming tide, and towards the sea, on the outgoing tide, gradually becomes less distinct at greater distances from the outlet, and disappears entirely within a distance of one and a quarter miles."

The material is distinctly visible and described as "offensive" in this report; such material it is as would not be retained by screens nor by settling basins; it is material which floats upon the surface.

That is a sample or type of the local nuisances which exist to some extent in New York harbor to-day, and which we believe would very probably result from the discharge of the Passaic Valley sewerage under the plans proposed.

With regard to the exhibit of bottled experiments that I offered you—Mr. Hering brought up the question whether solid matters did deposit more rapidly in sea water or fresh water. I offered that exhibit to show you, in a graphic way that sewage sludged or deposited more rapidly in sea water than in fresh water. The experiment may be easily repeated by any one; it was done
290 in this way: Sewage sludge was taken, in equal quantities, and put into each of two bottles; one bottle was then filled with sea water and the other with fresh land water; the bottles were allowed to stand; at the end of the periods of time indicated on the photograph cards the effects, which can be noted, were photographed.

Mr. Hering has indicated that Mr. Fowler, connected—Dr. Fowler, connected with the Manchester Sewage Disposal Works, has, I think, an opposite view. I would refer your Board, for substantiation of what I was saying, to an appendix,—appendix number eleven, of the report of Mr. John Sylvester Freemen to the Committee on the Charles River Dam, Boston, 1903: I can briefly say that there are photographs reproduced there which illustrate, and in more exhaustive manner, and with various changes, what my photographs showed you yesterday, and I would ask permission to read this brief statement, from page 286:

"In the course of this investigation, and in connection with observations of the appearance of the river at present during times of storm, certain experiments have been made upon the comparative degree of rapidity with which bodies of turbid fresh water and turbid salt water clear themselves. It has been shown very clearly that salt water acts like a precipitant, especially if the turbidity is caused to some extent by bodies such as are present in sewage * * *

This is true if the matter causing turbidity is well mixed with the water. * * * If turbid fresh water is placed above salt water, the turbidity will disappear slowly when the water is quiet.
291 This effect is shown by the photographs;" and so on.

Those are documents which are well worth very full consideration.

With respect to the kind of turbidity produced by my experiments, and with these (indicating book previously quoted from), I would ask you to consider that the solid matters are not such as would be removed by screening, nor by simple sedimentation for the brief period which Mr. Hering has indicated, so far as we understand his meaning.

The Mercey and Elbe rivers have been described as places where quantities of sewage were being disposed of without injurious consequence,—in fact, without being visible. I would ask you to consider that they are both turbid rivers, particularly the Elbe, and that experiments have been made, and analyses of the Elbe, which show that, although the sewage is discharged only on the outgoing tide, evidences of it are clearly discoverable at the water works of the city considerably above stream.

It is not a question alone of producing wholesale nuisances throughout these harbors that objection is made to increasing the amount of sewage pollution. The question of extensive local nuisances is one of very considerable import.

It has been urged that cost—Mr. Hering said, that cost should not control in this matter—The Metropolitan Sewerage Commission would urge that you give considerable weight to that point.
292 If there is no other reason than cost—if there is any other reason than cost to prevent the purification of the sewage or the handling of it in other ways without discharging it in the raw condition proposed, we believe—we do not appreciate it.

We believe that the disposal of the sewage under water in the manner proposed is in the nature of an experiment, and, although we are not prepared to say to what extent the harbors and channels will be silted, nor to what extent precisely other injuries may come to navigation or to the public health, we believe that safety requires that no question of doubt be allowed to attach to that matter.

I would also ask you to consider that there is a difference between the discharge of the sewage at the Passaic outfall and into rivers, in this respect at least; that, whereas the discharge of sewage into a stream running in one direction, may load that stream with, for the time, we will say, uniformity,—with a current such as flows backward and forward in New York bay, the water would get a double dose of sewage, or, at least, some of it would. The current which flowed up stream towards the end of the tide would return and get its second dose on its way towards the sea.

Mr. Hering, and I think perhaps others, have suggested that experiments be made to give us more light upon this uncertain question of diffusion. We know very little about the phenomena of diffusion,—of sewage in salt water particularly. The Metropolitan

Commission considers that a heavy burden rests upon it for
293 ascertaining some of those essential phenomena. If it is admitted that we know little now about those matters, we think there is more reason for considering that uncertainties attach to the projects of discharging the sewage in accordance with the proposed plans of the Passaic Valley Sewerage Commission.

Mr. Sandford: Gentlemen: I am not here under pay. I am not here by invitation of the Sewerage Commission. I am not here by invitation of New York City. I have a diversity of interests that are affected in various ways by this question of sewage. In the first place, I am the owner of three different tracts of land on the Passaic River. The sewer, if built, passes through lands owned by me for seven hundred and fifty or eight hundred feet. I am in the contracting business, and have vessels and boats in the Passaic River. I am the president of the New York Lighterage Company of the City of New York; we have vessels here. I also have interests in coast-wise vessels.

Now, it would seem to me—I have heard these discussions from the beginning—it would seem to me that the gentlemen—that a commission of the City of New York and one from New Jersey should get together on this matter and determine what is best at the present time and for the future,—not forever.

We know, about twenty odd years ago,—not over twenty-five years ago, the City of Newark spent a good deal of money building a sewer down into Newark Bay. That don't answer the purposes to-day. Now, they are asking the others to join with them and make a better arrangement. Now, this may be good for ten
294 or twenty years and after that we may need something else.

Now, I have heard Mr. Eastwood, of Belleville. I own property there myself. He told you about the houses being affected,—the paint on the houses. The gentlemen here the other day told you how the paint was affected on the boats. Now, I don't want to have this matter cured up in the Passaic River, if it is going to come out here and take the paint off of my boats here. Now, that is one of the conditions.

Now, twenty years ago I lived in a residence on the Passaic river at Belleville where we pumped the water out of that river and used it in our homes. Eighteen years ago, about, the gentleman—I am sorry that gentleman from Orange is not here—Orange is a progressive city—they built, eighteen years ago a sewer, and their receiving chamber is in the City of Newark. Under the laws under which that was built—and I know particularly about it because I was a bidder on this work—they were to store this sewage in this receiving chamber and let it out when the tide was ebbing,—but they have gone ahead of that. They have progressed!! They have abandoned the Moon Island plant and have gone over to the "Deer Island" plant: they let that out one day, and then lost the key and have never been able to close the gate since. I left my home (when that sewer was being built, I moved to Newark while it was being built) at Belleville. I live over in Orange to-day. The argument
295 was: There was very little building below there, and if they let it out on the ebb tide there would be few people affected

thereby. But, they did the other thing. They allowed it to flow at all times of the tide, and, therefore, they are one of the chief polluters of the Passaic River. At Belleville, the very town that they are polluting to-day, I own three houses on the river, where I have tight cess pools and tight water-closets, and it costs me Thirty dollars every little while to have them cleaned out; but this gentleman from Orange, this progressive man,—he puts his filth down there, and it floats by and down the river before those houses.

I don't believe these gentlemen have any objection whatever to those gentlemen of Orange having a filtering plant such as that which he suggested, on the Meadows,—we have one now in Newark, and the people have had them before a jury a number of times because of the way they take care of that. If they want one, let them build a system out of the city of Newark; we will get along without them. But let them put their filtering plant—their filtering basin up in their own territory.

Now, gentlemen, we are all identified in some way or another. I have, among other interests, an interest in the New York Horse Manure Company, that takes the manure off the streets of this city. We own our own floats; we own our own dumps, our own storage land. We take the manure every day from this city and take it out of your jurisdiction and over into New Jersey; we stored it on the Hackensack river up to about one and a half years or two
296 years ago. You had a smelling committee over here in New York which discovered that heap of manure, and one of the arguments they used was that the Pennsylvania had cars stop near that manure heap and that the flies got into those cars and were carried to New York. They didn't think anything about all we carried out on those manure cars. It was the flies that left the manure cars and got into the other cars. Now, what is the consequence? We were driven to the woods! We had to go out on the Rock Hill Branch of the Pennsylvania Railroad and buy a piece of land; here we were using land over there that belonged to the railroad company and didn't pay a cent of rent for it; we have had to put in a great system of tracks for it, and all of that is of vital importance to me because, on account of the great expense this year we have not been able to pay a dividend.

Now, gentlemen, we have all got to help each other a little bit in this matter. As I told you, I don't want this sewage to come down here and in place of taking the paint off of my Belleville houses, to take the paint off of my boats, if possible; but when you go up there and see that little stream of water and see the immense mass of filth that it is expected to carry,—no larger until it goes from Passaic until it gets to Newark, and the water supplies have cut off the entire flow of the river, and all we have to-day to take care of this sewage is simply the water that flows in from Newark Bay. That is all that we have to take care of all that sewage.

There are so many things to be said, gentlemen, but I have
297 just brought this thing to your attention, perhaps in a different way, and it is a matter I know something about. I have lived on that river. I have been around New York for the last

forty or fifty years, and I think I know the situation pretty nearly as good as any one else. I haven't any photographs, nor anything in bottles!!! I am only giving you plain facts.

Mr. Lebkuecher: I understand that Mr. Hering feels that perhaps some of the remarks in regard to disposal have not gone into the records just right, and have perhaps been misrepresented by the opponents, and he would like you to give him an opportunity to make that clear.

Mr. Hering: Mr. Chairman, I understand, from members of the Commission, that some of the opinions I have stated were evidently misunderstood, and I would like very emphatically to have you understand just what I do think in this matter.

I am, without the slightest question, and with no hesitation, in favor of this method of disposing of the sewage of the Passaic Valley which has been recommended by the Commission; as being by far the best solution of this problem.

I have stated that, so far as the expense was concerned, I believe, from present indications, that it would be more expensive to dispose of this sewage in the next-best way,—but it seems to have been misunderstood in this way: that I said the first cost of installation would be less than with this system; but the cost of operation is so
298 large that when you take the entire cost of the problem,—the interest on the investment, the depreciation, and all of the fixed charges, and add to that the very high cost of maintenance and operation, that it would be more expensive, decidedly more expensive than this system here. I do not think that it is cheaper, irrespective of the fact that we have got a good deal to learn yet about the details.

Dr. Soper: Mr. Hering, didn't you say that that question of expense should not be a controlling incident?

Mr. Hering: I did say that.

Dr. Soper: And that you are not considering expense in this matter?

Mr. Hering: I did say that, and I wanted to advert to that now. Our experience in this matter is confined to Europe and the United States, and this whole question of sewage purification has been one that has changed its aspect every few years; and we have not reached yet a finality.

I do not believe that over the whole situation of Newark you would find an available spot to-day for putting works of this kind; and I do not believe that is a very permanent institution. I am strongly of the belief that the people would object to it and that you could not put up works of the kind there; and I believe that they would have good reason to object, because that whole territory would be depreciated in value. I count that very highly.

Then, another thing, which is still more important in my
299 estimation. When you have a work of sewage purification, it means constant attendance—constant study of how to purify this sewage at this moment in the best way; it means an intelligent management; there would have to be a force,—a large organization to conduct a work of this kind; that brings in a city department,

almost, into existence, or some part of a department, to run this thing.

Now, I have always felt that cities should be recommended that which is most simple—taking that point of view, that is, decidedly, the simplest solution for a large public work; it does not require any large force for attendance, (and you do not know whether they are always going to do everything just as it should be done) whether you are not going to get an odor, which is particularly objectionable, or that something won't go wrong. We find that even in well-regulated Europe, and, therefore, that has always been a very weighty consideration with me, for if I could dispose of the sewage in a simple way—particularly by dilution—I would always do it even if it was more expensive. If it was more expensive even, I should recommend this system than to have a work of purification, provided it cost no more, than would accrue in this case, and I only see disadvantage. I do not see any advantage in the ultimate result over this, and I see the disadvantages of the large force of operation as well as the disadvantage to the people living around it, even though they lived half a mile away from it.

Therefore, I am absolutely of the opinion that this is decidedly the best system for the territory to adopt, and I should not like to be misunderstood in that matter.

The Chairman: Is there anything else?

Mr. Hering: Now, I should just like to reply a moment to Dr. Soper, with reference to those jars of sewage—I refer to the settled sewage where all the suspended matter is deposited first, and that is that Dr. Fowler speaks of; this is not settled sewage; this is raw sewage.

Dr. Soper: I beg your pardon, this is settled sewage.

Mr. Hering: Well, then, you will have to settle that with Dr. Fowler.

Dr. Soper: I know him very well: I should be pleased to.

Mr. Hering: Another point is, I would like to mention, and that is about the flies. It was brought up twice. Now, gentlemen, the last thing I heard of in Europe this Summer, and this was in England, they were claiming how fine they were getting along,—that there was an odor, but faint, "But the flies!!" There has never been such an exhibition of flies in England or anywhere, than since these disposal systems have been introduced. They fill the contact beds; they breed right under the stones. You pick up a stone, perhaps, and under the edge, under a little bit,—all flies. We know that there are flies in connection with these plants; there may be a way of over-coming that feature; it has not been thoroughly demonstrated as yet; there are flies, floods of them in every plant and complained of very generally. Therefore, the fly question could not be used as an argument in favor of this system of sewage purification. I have not the slighest doubt there will be found some means to reduce that evil, so I do not place any weight on it, but it is an actual fact that a splendid breeding place for flies is right under the stone.

Then, too, one thing more: that is what Dr. Soper said about the

tidal stream coming up and getting the sewage and going back and getting a double dose. Now, that is perfectly correct,—but that is provided for in making a very liberal estimate of the dilution, and I would like to say this: that is no worse than storing the sewage,—holding it back until the out-going tide and then letting it go out in the out-going tide, because, then, you get a double mass of sewage on the out-going tide. It has been found better not to store up the sewage. There are exceptions to that case, but it is better to let it be dispersed and go up and down with the water, as found finally in Boston.

Mr. Schondelmeier: My name is Schondelmeier: Physician. I represent the Broadway Buyers trade and the Right Buyers Trade, of Brooklyn.

This matter of sewage has been under consideration for quite a time in these boroughts. It is a subject we all know is growing in interest, and is forced upon us.

I will not take up your time by repeating what has been said yesterday and to-day; that it is objectionable,—that it would
302 be objectionable if this trunk sewer were constructed and the sewage emptied into the Bay. I will just mention a few cases that are proof in evidence in this day that sewage plants can be constructed and operated satisfactorily. I will refer you to the sewage plant of Elmhurst, which is just above the Flushing Bay a short distance; it does its work so perfectly that as the water leaves the plant it is as clear as the water on the table which we use for drink.

We have another illustration in the sewage plant of Saratoga, where, as the water flows out into a small stream of water,—first into a large stream, located below the plant, algae develops there and other plants grow right in the water,—water coming out of the disposal plant after having been filtrated—so that it is possible to putify,—to withdraw all adulterous material from sewage. It is merely a matter of expence and wanting to do it. Saratoga has laid the problem by, as I have been told, by paying about two hundred thousand dollars for the plant, and is now running it constantly at an expense of two thousand dollars a year.

The plant at Elmhurst is minus the flies. I have proven it to my own satisfaction by having investigated it. There are practically no flies there. There is very little odor there. If those things are possible, and right near by, where it would be as reasonable to offer as an excuse that "We have not the land" and "We have not the room to institute the plant"—for they certainly have. The room is there in Jersey, as they intend to carry the sewage over twenty miles above the Bay here, right near our river-front, we
303 are disposing of it in a proper, sanitary, method.

Therefore, we do feel, and in offering this protest we offer it emphatically and earnestly, we do feel that the efforts that are being made by the City of New York and by organizations interested in the disposal of sewage in a proper way,—we do feel that others should encourage us in this work, and not ask us to permit them to do what we are endeavoring to overcome ourselves.

Mr. Lebkuecher: May I ask the gentleman what efforts the City

of Brooklyn, or what efforts the City of New York has made,—what has been done towards a sewage disposal plant in the City of Brooklyn?

Col. Knight: I fear you misunderstood him; he referred to the efforts made at Elmhurst.

Mr. Lehkuecher: I did misunderstand him.

Mr. Child: Mr. Chairman, and Gentlemen: In the few remarks I desire to make, I propose to discuss entirely the questions of obstruction to navigation. I have been living in an atmosphere of sewage for the last seven years, and the mere mention of it gives me qualms of the stomach; and I have no desire to discuss that.

As I understand it, the province of this Board, the peculiar jurisdiction of the Board is to see to it that navigation is not interfered with, either by improper construction or in any other way.

I also understand that in considering the question of the wants of navigation, that this Board will take a broad, comprehen-
304 sive view,—not confine itself to the limited section in the immediate neighborhood of Robbins Reef Light, but will look over the whole field.

It is known to you, gentlemen, that the Newark Bay is a very considerable body of water. It is known to you that the Passaic river is a navigable river for many miles up from the Bay and that the commerce of the Passaic river is very great. It is also known to you that you have had probably as much trouble in keeping matters in a proper condition in the Newark Bay and in the Passaic river as in any other territory under your jurisdiction.

Now, you cannot but say that this improvement—and we call it an improvement, and advisedly so—that this improvement will be in the interests of navigation so far as the Newark Bay is concerned, and the Passaic River. We will take out and we will keep out of that river the very things which make your task in keeping navigation open throughout that territory so difficult. That is one thing.

Now, in the next place, it is alleged, and that is all, it is alleged that some obstruction to navigation may result at the outfall of this sewage. It has not been shown that, in the Metropolitan District of Boston, any such obstruction has resulted. No complaint has been made by the Harbor Line Board having charge, unless you gentlemen may have, having charge of that territory. No one has shown to you that any result, so far as navigation is concerned, no injuries, have existed in connection with work of this character; so that you have, what? On the one side, a certain, positive
305 benefit to navigation over there in the Passaic Valley and in Newark Bay; certain, sure, unquestionable. On the other side, you have mere speculation of something which may possibly occur. Nothing has occurred in the whole history of trunk sewers,—in England, all over this country: No one has shown that it ever had occurred but it may occur.

Now, gentlemen, right in that connection, criticism has been made because these plans are said to be insufficient in detail with reference to the settling basins, the screens, and the outfall pipes.

Now, is there any uncertainty? That which can be made certain, is certain. It is certain!

This application which is pending before you is almost an exact reproduction of the application presented by the Metropolitan District (of Boston) to the Department for permission to locate each of their sewers.

Mr. Brown, who is in charge of that great Boston work, has been in our employ for years. He has been one of our consulting engineers; and, at my request, Mr. Brown sent us a copy of the last application that was made for a trunk sewer in Boston; it was on the exact lines with this, using the identical language.

Now, what do we do? What do we ask? And, before coming to that—I may be ignorant, and, if I am, I am willing to be instructed,—but I do not understand that, when the Department at Washington, acting on the recommendation of this honorable Board, grants its permission, that its jurisdiction is gone.
306 I do not understand that. It is to be only a permission: It is not a grant. It is always within the control of the Government.

Now, what are we asking? We are not asking, as has been asked thousands of times, and, I suppose, a great many times, of you, gentlemen, a right to obstruct navigation. We do not propose to take from the navigable waters any space at all. We are not proposing to build out bulkheads, extending the lines of bulkhead and pierheads: But, what are we asking? We are asking the privilege of constructing a sewer, which we represent to you will not result in any obstruction to navigation. If it does obstruct navigation, then we will stand shorn and naked of all rights coming to us by virtue of this consent, because no plea of ignorance of right principles of construction could possibly avail.

That is what I understand to be the true position, and no other position would be safe. I take it that, if the Commission should be given this consent, and we should construct a sewer and it should prove an obstruction to navigation, in the harbor of New York, in these waters, why the power is in the Department to do one of two things: Either to compel us to stop using the sewer, stop creating the obstruction, to change our plans, and to remove the obstruction.

Now, what risk does anybody run? We propose to put Twelve million five hundred thousand dollars into this project as an assurance to you gentlemen, representing the Government,
307 that we are acting in good faith; that we have faith in our representations to you, as made to you, and with the full knowledge that if those representations are false, we take nothing.

Now, what do we do? In this application, we provide here, and in the plans, and in the report which is submitted, which is made by our Commission, we are bound by every representation I have made, as well as every matter which is alleged here in this petition.

Now, what do we say? "All work in or below navigable waters, both permanent and temporary to be subject * * *"—to what?—

"to the approval and supervision of the United States authority having jurisdiction over the said waters."

Now, suppose we should—assume that our representations are false,—assuming we should construct these works without screens, without a settling basin, and that we should discharge our sewage raw, and containing heavy matter, and that it should result in an obstruction to navigation: Why, there is the authority,—we have got to get out!

There are many things of this sort that are of no use, that cannot be determined definitely, until the thing is done. But, when a man comes before you, and who claims to possess the requisite knowledge,—the man upon whom the loss, if any, must fall by reason of his failure, if it proves a failure, and he is willing to put up as an evidence of good faith an investment of over twelve million dollars, to give this Board, or the proper authority a bond which will compel us to remove each and every thing which this Board will determine to be a nuisance,—How does that
308 become a question of such great moment? The size of the settling basins! The size of the screens!

But, we go farther than that; and we want you, gentlemen, to tell us, after we have constructed the settling basin, after it is all done, and after our money is in it, if it is too small, and, if it is too small, we will make it larger,—and we will keep on increasing the size until you are satisfied.

As compared to a twelve million, two hundred and fifty thousand dollar expenditure, why, that is a bagatelle! It amounts to nothing! A piece of masonry, the size of this room, compared with the expenditure of twelve million, two hundred and fifty thousand dollars! So that that is simple enough.

It is the same thing with the screens. Why, with this bond, and with this conditional assent (because it is nothing else) it is more to our interest, having all this money at stake, to see that proper screening is effected than it can possibly be to any community, let alone any individual. Because, assuming—assuming these gentlemen who are so filled with fear and apprehension, that it may be that their fears may be realized within a reasonable time, —why, how simple it is to remove it!

Now we come, for instance, to distribution,—to the arrangements for distribution at the outfall of the plant. I do not know anything about it (and as I have heard these engineers
309 testifying here I was almost glad I did not know anything about it), I do not know whether one pipe, or five hundred pipes may or will be necessary; but, gentlemen, if five thousand pipes are necessary, we are prepared to put them there.

Now, that is all. Now, what more can we do? We say here now,—I say that all we say here, all I say, this binds us, and, as a member of this Commission I acknowledge the obligation imposed upon me when this application was presented to you gentlemen.

Before the sewage enters the pumping station it passes through a grit chamber to remove all gravel, sand and other heavy matter,

and through a screen chamber, where all floating matter will be removed. Now that is the proposition. Now, if we do not do that, then, when the time comes, you withhold your sanction and we will rest content.

It seems to me that the question is of no possible importance. It cannot be told now, as these engineers say. Well, they know more about it than we do (of course, I ought not to say that, because you gentlemen are skilled and learned in these engineering matters,—but I meant myself), but, whether they do or not, I do not know; but they tell us that they have got to wait in order to determine this. Now we will wait, but we are waiting all the time, —all the time! The grip of this Board,—the grip you gentlemen have on us is not relaxed at any time. Your successors, if there should be such, five years, ten years, from now,—indefinitely, now and then, will have exactly that authority.

310 So that I do think, gentlemen, with all deference to the various discussions that have been made, that these two matters are provided for, and that they are provided for in the best and the safest way.

What greater assurance could the Metropolitan District—and these plans are identical, as I have said—give to your Board than that it should be something which you, gentlemen, selected on account of your peculiar ability, with your knowledge, acquired after years of experience, and with your special education, should say was safe; that it was sufficient? Could any jury be selected to decide a question of this nature, more competent, or better qualified to determine such a matter?

But we will give the bond as an additional assurance; and we known that the Government will not refuse a bond——

The Chairman: Well, we don't know as to that, Commissioner,—probably you do——

Mr. Child: Well, that is my point-of-view, being unfortunately a member of the legal profession,—I have had a great deal to do with the legal matters connected with this case, which I do not propose to discuss at all. There is a tribunal before which it must be discussed before long, and Mr. Dean said that he trusted that you gentlemen would defer your decision of this matter until adjudication had been had by the Supreme Court of the United States on the pending litigation between New York and New Jersey.

The questions involved in the litigation in the United States Supreme Court are entirely foreign to any question pre-
311 sented to you, gentlemen. The question which you are called on to determine, as I understand it, is whether this proposed work will be an obstruction to navigation. Whether it is in the State of New York or in the State of New Jersey is of no possible materiality. If it is an obstruction to navigation, you gentlemen would refuse your consent if the application was made by New York or by New Jersey or if made by both, provided you believed that that would be the result.

That question is not involved in the litigation in the United States Supreme Court at all: That is purely a question of sovereign

right. To withhold this until after that decision would be, I think, a manifest injustice to my Commission. Because, there is a great deal of preliminary work which must be done in any event with reference to the construction of this sewer. Because drawings are to be made, in greater detail, of all things, and contracts prepared, ready to be put out in proper shape, and all matters of that kind, which we assume will take us from eight to ten months, and will involve the expenditure of a large amount of money.

The condition, as you heard it described here, is terrible, and ought to be abated with reasonable celerity. Now, to hold us back until the Supreme Court of the United States, acting with reference to the litigation of other questions, should render their decision would be, gentlemen, I submit to you, gentlemen, tantamount to a denial of justice. If we are entitled to it, then we ought to have it. If we are not entitled to it, then this Board ought to
312 declare that. And then, of course, some other procedure will have to be resorted to for temporary relief,—or we must bear the ills we are now subject to.

And as in this litigation the animus of the suit between New York and New Jersey being solely with reference to the suppression of this sewer,—if you should (I do not anticipate it, and do not see from my standpoint, how you can do it), but if you, in your wisdom, should determine that we are not entitled to the use of that which we are here asking for, that decision on your part would in no way affect this case,—it could not possibly have any influence upon the pending litigation in the United States Supreme Court,—that is, so far as this Passaic Valley Sewerage Commission is concerned. I presume that, the object having been obtained in another direction, it would lead to an abandonment by the State of New York. So that there is every reason to conceive of why the decision, and a reasonably quick decision, should be reached now.

It may be said now that all matters of etiquette and propriety must be decided by each individual for himself; and, of course, this Board is able to decide any question of that character. Now it may be that at first thought it will appear that it would be discourteous to the United States Supreme Court to anticipate their action. Now, as against that, I have this to say: That we were first in the field. We made our application before the suit was brought, and, on the other hand, if we had not made our
313 application to your honorable Board, the suit would not have been brought; when we made the application, the suit was brought.

And then, inasmuch as this question is not before the United States Supreme Court, and cannot affect—either directly or indirectly—so far as the legal considerations are concerned—any decision which they may reach, I do not see how it is a violation of any of the rules of strictest courtesy.

Of course, if you consider the character of that tribunal, and of the honorable body of men sitting to-day in the United States Supreme Court, it would be folly for any man to believe that they would be influenced in their determination of a question of right,

by a conclusion reached by another tribunal on another and independent point.

Now, with these remarks, gentlemen, I am through; thanking you for the courtesy of your attention. I trust that this Board will see its way clear to grant to the State of New Jersey,—the important part of the State of New Jersey, the relief so imperatively demanded.

Mr. Lebkuecher: May I be allowed to ask Mr. Riker to make a few remarks?

The Chairman: On this phase of the question?

Mr. Lebkuecher: Yes, sir.

The Chairman: I do not think it necessary, that is, if I understand it to be in duplication or reiteration of what has been said——

Mr. Lebkuecher: Merely for the purpose of strengthen-
314 ing it——

The Chairman: I do not think it is necessary. Do you undertsand that if there is anything further to be brought out, the Board is prepared to continue this session, tomorrow, if necessary.

Mr. Lebkuecher: I think we are about through, Mr. Chairman; we have nothing more to present.

The Chairman: Gentlemen, is there any one here who desires to say anything more on this question? The Board desires to give everybody an opportunity——

Mr. Sandford: One remark I would like to make is that I do not know whether the gentlemen are aware that the United States Government, at the present time, are spending a great deal of money on the Passaic river, to make it navigable for larger vessels——

The Chairman: That is entirely within the knowledge of the Board.

Mr. Sandford: I wanted to say, in connection with that, that unless we can get factories and warehouses and so forth, along that shore, where people can work in, why, the deepening of that river will be lost to the community.

Mr. Lebkuecher: Have you all of the data you require, from our Commission?

The Chairman: Everything that has been handed to the Board——

Mr. Child: I do not know as to whether I was understood this morning, when I handed you the extracts from the United
315 States Coast Survey Reports,—I spent considerable time over the Coast Survey reports, and I think you will find them very interesting. They cover all the principles of New York harbor, as to currents, and so forth. I am not going to refer to all of the different data, but it is a comprehensive index to the Bay.

The Chairman: The Board will be prepared to receive any communications bearing on this subject at any time up to and including Monday——

Col. Knight: Why not make it Monday a week, and give them ample time——

The Chairman: Up to and including Monday, December 21st.

The hearing is adjourned.

Complainants' Exhibit No. 2. James D. Maher, Commissioner.

State of New York:

W. J. Sullivan.

Report of the New York Bay Pollution Commission to Hon. Frank Wayland Higgins, Governor, March 31, 1905.

Commissioners: Daniel Lewis, Chairman; Olin H. Landreth, Myron S. Falk, George A. Soper, Louis L. Tribus, Secretary.

Transmitted to the Legislature May 1, 1905.

Compliments of the New York Bay Pollution Commission. Louis L. Tribus, C. E., Secretary, 84 Warren St., New York City, Oct. 1905.

(Here follows map marked page 1, Exhibit No. 2.)

3 STATE OF NEW YORK:

W. J. Sullivan.

Report of the New York Bay Pollution Commission to Hon. Frank Wayland Higgins, Governor, March 31, 1905.

Commissioners: Daniel Lewis, Chairman; Olin H. Landreth, Myron S. Falk, George A. Soper, Louis L. Tribus, Secretary.

Transmitted to the Legislature May 1, 1905.

4 STATE OF NEW YORK:

No. 39.

In Senate, May 1, 1905.

Report of the New York Bay Pollution Commission to Frank Wayland Higgins, Governor of the State.

Commissioners: Daniel Lewis, Chairman; Olin H. Landreth, George A. Soper, Myron S. Falk, Louis L. Tribus, Secretary.

Hon. Frank Wayland Higgins, Governor State of New York, Albany, N. Y.

SIR: The New York Bay Pollution Commission respectfully reports to you herein the main facts concerning its researches and its recommendations.

6 Causes Leading to Appointment of Commission.

The State Department of Health, having for years noted with anxiety the increasing pollution of New York harbor, due to the discharge into its waters, of sewage and factory wastes of all kinds from the different boroughs of the city of New York, the city of Yonkers, and the cities and towns in the State of New Jersey, situated along the banks of the Hudson river, New York bay and their tributaries and estuaries, and this pollution having culminated in the proposed construction of an immense sewer to discharge the waste from a large territory in New Jersey, not contiguous to the waters of New York bay, brought the matter to the attention of Governor Odell, who thereupon invited legislative action.

The Passaic river (lying wholly within the State of New Jersey) but flowing into one of the estuaries of the harbor, became years ago so foul with sewage coming from the cities along its banks, that a serious nuisance was created, menacing the health and comfort of the adjoining and lower communities. It discharges into the tidal waters of Newark bay, which opens in turn into Staten Island sound and Kill von Kull; thence into New York bay, respectively the lower and upper portions, though as yet these latter waters have not evidenced a condition where annoyance is strongly apparent;—Newark bay having acted as a diffusing, settling and partial purification basin;—but with the possibility that a nuisance will be created.

The State of New Jersey had authorized the preparation of plans and the issuance of bonds for constructing a large trunk sewer which, when completed, would free the Passaic river and Newark bay in large measure, from the sewage of Newark, Paterson, Passaic and many smaller communities within the drainage area.

7 The plan proposed to conduct all this sewage across Newark bay; thence across the city of Bayonne, and empty it into New York bay within the State of New Jersey, but near the interstate line, on the margin of the deep water channel, at a point about one mile north of Robbins Reef light.

There was thus contemplated the discharge of the house wastes and factory refuse from a population of between one and two millions of people, directly into New York harbor at one, two, or three points, located near together.

Opposition to the project which has developed in the State of New Jersey need not be considered in this report, though upon various grounds it has been considerable.

Legislative Action, New York State.

The subject was brought to the attention of the New York Legislature of 1903, which forthwith enacted Chapter 539, becoming a law May 11, 1903, entitled "An act to authorize the appointment by the Governor, of a commission to investigate certain threatened pollution of the waters of New York bay and making an appropriation for the expenses of such commission."

The salient points of said act being (abstracts as follows):

Section 1. Authorizing the Governor to appoint a commission of five members to serve without compensation.

Section 2. Directing said commission to confer with the authorities of the State of New Jersey; to take testimony of witnesses and make such investigations as should seem desirable to determine the character of the threatened pollution, if any, and the means necessary to effectively prevent the same.

Section 3. Giving power to said commission to administer oaths, subpœna witnesses, and such other powers as Article 3 of the Legislative laws gives to Legislative committees; and requiring the commission to report to the Governor the result of such investigations and its recommendations as to legislation, etc.

Section 4. Appropriating moneys for the necessary traveling and other expenses of the commission.

Section 5. Making the act effective at once.

Work of the Commission.

On June 2, 1903, the appointments of the commissioners were forwarded, and on the 30th of that month the first meeting was held, at which an outline of procedure was prepared and assignments made to the different members, of subjects for their special investigation.

As appendices to this report will be found in full these special reports, which have been fully discussed at the meetings and from which, with testimony taken at public hearings and joint conferences with the Passaic Valley District Sewage Commission have been derived the conclusions.

The Special Subjects are as Follows:

Appendix 1. Tidal action and river flow in harbor of New York, by Commissioner Myron S. Falk.

Appendix 2. Present sources and estimated quantities of sewage coming from different communities in and about New York harbor, by Commissioner Louis L. Tribus.

Appendix 3. Sanitary and bacteriological analyses of New York harbor waters and fisheries; and industries affected by pollution, by Commissioner George A. Soper.

Appendix 4. (A) The history, laws, reports and plans of the New Jersey project, and (B) ocean disposal as a possible solution for all the metropolitan sewage nuisance, by Commissioner Olin H. Landreth.

Appendix 5. Needs of the metropolitan district as a whole and desirability of joint State action, by Commissioner Daniel Lewis.

Appendix 6. Legal rights and powers of New York State to prevent pollution, by Attorney-General John Cunneen.

In addition to these special reports there will be found herein:

Appendix 7. Law authorizing appointment of commission.

Appendix 8. Proposed Legislative bill.

3061

Appendix 9. List of meetings held by the commission and special features considered thereat.

Appendix 10. Statement of disbursements.

Appendix 11. List of those who have rendered special assistance to the commission.

Map, showing: Tidal action New York harbor (see Appendix 1).

Sewer outlets at margin of harbor waters (see Appendix 2).

Shellfish beds and position of points from where water and shellfish samples were taken for analyses (see Appendix 3).

Passaic valley sewerage district and proposed location of outlet (see report of New Jersey Passaic Valley District Sewerage Commission).

There also will be filed at Albany full minutes of the different meetings, both in executive session and in joint session with the New Jersey authorities, and a copy of the report of the Passaic Valley District Sewerage Commission, and testimony of experts retained thereby.

10 In connection with the joint investigations, a number of personal studies have been made by different members of the commission, of the most recent systems of sewage treatment and disposal, so that possibilities of other means of disposal than at present planned by the State of New Jersey could be intelligently considered, though it has not been thought proper to suggest any special course for New Jersey to follow.

Tidal Conditions, New York Harbor.

Assuming that the Passaic valley trunk sewer has been constructed with one, two or three outlets north of Robbins Reef light, the action of the tidal currents would very largely determine the question whether the sewage discharge would be likely to become an offense to the senses or not, even considering that the sewage would ultimately become diffused, and that the water in the harbor is sufficient to safely and rapidly dilute so large a concentrated flow. If the sewage should be discharged at a uniform rate throughout the twenty-four hours, as has been contemplated by the Passaic Valley District Sewerage Commission, it is unquestionable that some of the sewage would be carried by the inflowing tide northwards into the Hudson and East rivers, and on the outgoing tide southward to the shores of Staten Island. If the sewage should be retained so as to have the outflow only on the stronger run of the ebb tide, the percentage to go northward would be greatly reduced, helping the upper harbor, but the percentage reaching the shores of Staten Island would be greatly increased; and though the total quantity of sewage in twenty-four hours would be no greater, it would be discharged in practically eight instead of twenty-four hours; so that the quantity at any given time during the outflow would be three times as great as on a continual flow basis.

11 A matter of much importance in considering the dispersion of sewage is the question of the under-run of salt water beneath the fresher waters from the Hudson. The difference in specific gravity between the two waters may be as high as 2½ per

cent. There is thus a tendency for the salt water to force itself up the river for a considerable distance and to remain stagnant while the fresher waters follow their way down to the sea. This tendency is marked at low water stages in the river. It does not seem improbable, therefore, that some of the sewage discharged at from 30 to 40 feet beneath the surface would even during a strong ebb tide for the upper layers of water encounter strong up-stream currents and be, therefore, carried well up the bay and even some distance up the Hudson river. The full effect of this under-current is not known, but its existence has been noted and it might almost totally vitiate the efforts to dispose of sewage from the proposed Passaic valley trunk sewer by means of tidal carriage and diffusion. It might be that for some years the collecting of this sewage in the potholes or basins of the bay and the river would not create a nuisance noticeable on the surface or in the great body of water, but it is certainly desirable to guard against such a possibility.

In any case, the subject is one more largely of tidal phenomena than straight diffusion, except as to the great probability of a local nuisance being created near the outlet pipes;—one which, if created, would be apparent from boats passing along the main channel to and from Kill von Kull; the ferry lines between Manhattan and Richmond, the many vessels anchoring on the west side of the main ship channel, particularly in Summer, and to many of the steamers and excursion boats passing in and out of the bay.

12 The expert advisers of the Passaic Valley District Sewerage Commission unite in the opinion that on a twenty-four-hour outflow the diffusion of sewage would be so great immediately on its entering the waters of the bay as to create no nuisance. They are less certain as to the effect of having the discharge during the shorter number of hours so as to make more use of the ebb tide. In the latter case they think there might be trouble, in the former they estimate that there will be none; scarcely a safe ground to stand on in a vital question.

It has been practically impossible to secure exact figures as to the tidal flow phenomena, though United States government engineers some years ago conducted a series of observations and tests. From them and such other data as have been secured, it seems probable that a quantity of water not far from twelve to thirteen billion cubic feet enters the upper bay at each of the tides per day. Of this amount, the approximate figures may perhaps be:

4,250 million cubic feet into the East river;

6,750 million cubic feet into the Hudson river;

1,750 million cubic feet into the Kill von Kull.

The areaas of the tidal basins receiving this flow are approximately as follows:

Kill von Kull, Newark bay, and the Passaic and Hackensack rivers about 14.2 square miles.

The Upper bay about 21.6 square miles.

The East river about 4.5 square miles.

While the Hudson river has a tidal area equal probably to all the others combined.

The ebb tide coming down the Hudson meets the ebb tide coming eastward out of the Kill von Kull; they both reach in and
13 strike Staten Island between Stapleton and Clifton, at a point distant about three to four miles from Robbins Reef light. It then makes along the shore and traveling along the beach makes Forth Wadsworth. At this same time there is also an ebb coming from Arthur Kill (or Staten Island sound) and Raritan river which, striking the main current, tends to throw it to the eastward again in the lower bay. In calm weather the force of the main tide through the Narrows may reach as far as Swinburne Island and Orchard Shoal. Strong winds at all times tend to deflect the currents somewhat.

The first effect of the flood through the Narrows is to strike the shore of Staten Island a little to the north of the point where the first effect of the ebb is felt. The second effect of the flood is reaching into the flats of the Upper bay to the west of Robbins' Reef. The third is to flow into the Kill von Kull, and the fourth and final effect to flow into the Hudson and East rivers. After the first of the flood the tide also travels up on the Brooklyn side. It is probate that in calm weather the maximum effect of the flood tide is felt on the northwest side of the Upper bay.

The tidal ebb is detected by discoloration of the water five or six miles from the outer face of the bar; sometimes even outside of Sandy Hook lightship, but there seems to be little concentration of effect, at that distance from the Narrows.

The published Government reports give the maximum ebb velocity of the current in the Narrows at 1.5 knots and the maximum flood 1.2 knots per hour. In the Hudson river off Thirty-ninth street these figures are respectively 2.7 and 2.0 knots, and in the East river off Twenty-third street, 2.0 and 1.8 knots. Estimating a constant velocity of discharge during the various tidal periods of the day, the average ebb velocity at the Narrows would
14 reduce to 1.61 miles per hour, the average flood velocity to 1.48 miles per hour.

It is probable that some of the sewage which reaches the radius of action of the active tidal ebb flow, will ultimately be carried out of the harbor to the ocean, though taking several days in the process, but it is not so evident that all of the sewage or even that the major part of it, will reach such radius of action, so would remain in the harbor for gradual putrefaction and breaking up.

If the diffusion and rapid oxidation should not be so great as is anticipated by the Passaic commissioners, it is not difficult to imagine the creation of a condition of affairs decidedly unpleasant to the senses, if not necessarily detrimental to health, particularly along the shores of Staten Island and in the path of many vessels.

Present Pollution of New York Harbor.

The Hudson river receives sewage from many of the larger cities and towns of New York State, which it discharges into the harbor of New York, but being affected by tidal action as far north as Albany, and the combined fresh water and tidal volumes so greatly

exceeding the total quality of sewage, no general nuisance has as yet been created, nor does such seem likely to arise in the near future. Some of the streams tributary to the Hudson do present, however, very serious conditions. The cities along the Hudson, south of Albany, are daily pouring their millions of gallons of filth into the river, but not creating as yet any noticeable nuisance, except near the outlets. To what extent this sewage undergoes organic change by the time it reaches New York harbor is a question difficult of determination. If a complete change does not take place,
15 so thorough a diffusion does occur as to prevent any serious nuisance being apparent. The condition is not so certain, however, as to the outflow from the several hundred sewers entering New York harbor at both sides of the Hudson river from the Yonkers line southward; in the various kills and bays, and in Long Island sound within the radius of action of the harbor's tidal flow. It should be said in fairness, that at the present day the waters of New York harbor in general are not so polluted as to be offensive to the senses, though such is the case in some of its estuaries and smaller bays.

Without elaborate study, no one can estimate with precision, however, the exact degree of pollution permissible, before the conditions would reach a serious stage. The following table gives estimates of the present normal daily sewage flow from existing sewers; that proposed (based on present conditions) from the Passaic Valley trunk sewer and that from another large system lately constructed, which will accommodate South Orange and other communities in that portion of New Jersey, as well as a considerable portion of the city of Elizabeth.

From locality.	Estimated present population.	Estimated daily dry weather sewage flow in gallons.
Communities on shores of New York Harbor	4,470,000	447,000,000
Part of Elizabeth and South Orange District	80,000	8,000,000
Part of Passaic Valley District	500,000	50,000,000
Totals	5,050,000	505,000,000

On the map accompanying this report has been indicated the outlet points of all sewers of which information could be secured, the table in Appendix 2 showing their respective discharges. Most of these accommodate storm flow as well as sanitary sewage.
16 Ordinarily, of course, they only handle house and manufacturing wastes and some street washings; but immediately following rain storms, a great deal of additional filth from the streets reaches the harbor, in quantity probably averaging some 350 million gallons per day. The normal pollution however may be considered, to be chiefly the outflow of house and manufacturing wastes, rejected by about five million inhabitants of New York and neighboring communities.

The saving feature of the present discharge is that it debouches at so many different points that very thorough dilution occurs and any great localized nuisance is avoided,—a condition which could not

be predicted if the whole flow should be gathered into five or six outlets, each having the capacity of the proposed Passaic Valley trunk sewer.

It must be borne in mind in considering all such matters as those made the subject of this report, that the best or even average conditions are not those which govern the case, but that the worst possible conditions which may arise are those which should determine conclusions; consequently, it is not the immediate plan of the Passaic Valley District Sewerage Commission which needs to be thought of as possibly dangerous, but the ultimate plan contemplated and not only with regard to the New Jersey project or projects, but concerning all sewerage works having present or proposed future entrance into New York Harbor and its bays or branches. In questions of this character, years must necessarily intervene between the initiation and the consummation of projects, so that future nuisance must be anticipated and relief measures considered many years before either the nuisance has been created or the relief can be given.

17 Sanitary and Bacteriological Condition of New York Harbor and Its Fisheries and the Industries Affected by Pollution of the Waters.

From the studies of the commission it is evident that the present pollution of New York Bay, although not great, is distinctly measureable by chemical and bacteriological analyses, and careful studies of the relative proportions of sea and fresh waters in the bay and rivers about New York show that the sewage of New York city is not promptly flushed out to sea, except perchance during time of heavy freshets from the Hudson. The water of the incoming tide is not ordinarily much purer than the water of the outgoing tide, as noted in the Upper bay, yet it is probable that most of the sewage now entering the harbor is disposed of in the harbor itself by the lower orders of animal and plant life found abundantly in the waters, the chief effect of the tide seeming to be the production of currents whereby the sewage becomes mixed and diffused. Without special and experimental studies it is impossible to estimate with clearness how large a proportion of sewage and other organic matter can be emptied into the harbor without killing these forms of life which now destroy it. Immediately follow- their destruction would unquestionably develop an intolerable nuisance. It is estimated that every 24 hours there is deposited from the sewers of New York and vicinity an equivalent of 1,047 tons of dry sludge, about one-half of which may be assumed to be organic matter.

The oyster beds of New York bay are almost exclusively found on the southeast side of Staten Island and in Gravesend bay. Most of these shellfish beds are now free from dangerous pollution,
18 though some of them are found to be nearer sewer outfalls than is wise or proper.

Analyses of oysters and clams made under the direction of the commission show that shellfish grown or immersed for some hours in polluted water, become polluted themselves. This fact is of peculiar

importance, for the custom is almost a universal one of taking oysters from their natural beds and depositing them for a few hours or days in the mouths of fresh-water streams adjoining the coast; streams which are almost invariably seriously polluted, the object being to give the oysters a so-called "drink" which results in bleaching and bloating them.

Fish caught in the harbor do not seem to have given evidence of impairment of their meat due to polluting matters, except at certain times in the past from special causes such as the outpouring of petroleum and other industrial wastes.

It is probable that about 1,000,000 bushels of market oysters and clams are taken from the waters of New York harbor annually, at an approximate valuation of about $900,000. The fishing of importance in the same waters, practically confined to the catch of shad in the very short spring season, which amounted in 1901, the heaviest year since 1888, to less than 3,500,000 pounds, valued at about $110,000. From these figures the question of interference with fisheries cannot be considered a very serious one from the industrial point of view should the whole industry disappear. Should disease, however, be disseminated from the eating of polluted shellfish before such time as the industry shall disappear from New York harbor, the consequences might be very serious.

There have been taken during the past season about fifty samples of water from the harbor, at points between the Battery and
19 Coney Island on one side, and the Battery and Raritan bay on the other. These were analyzed with the result that colon bacillus, an invariable accompaniment of sewage was generally indicated by the "presumptive test." These analyses were made in the Prospect Laboratory, Brooklyn, by one trained in water analysis. A few specimens were also sent for examination to the Bender Hygienic Laboratory at Albany. Some fifty-one specimens of oysters and clams were also taken from their natural beds and examined in a similar way for evidence of the colon bacillus. The results show that wherever the waters indicated pollution, the oysters were themselves found to share in the pollution; while in general the samples taken from the localities where the pollution of the water was not appreciable, were wholesome: the samples taken from the "drinking grounds" showed greater evidence of pollution than those from the natural beds.

Chemical examination of the waters made for this commission and by others show distinct evidence of pollution both at ebb and flood tides, particularly in the Upper bay, though the examinations do not warrant the opinion that the water is everywhere and at all times contaminated, but that traces of pollution can sometimes be found after the sewage has been thoroughly commingled with the waters of the bay and has traveled miles from its point of origin. The commission does not desire, however, to base too great importance on these analyses. Such analyses are rather indicative of lines of investigation than conclusive in themselves.

Concerning other industries likely to be affected by serious pollution of the waters, it should be noted that excursion steamers car-

ried in 1903 nearly 2,500,000 passengers to bathing beaches
20 and day summer resorts, on or near New York bay, where have been invested a number of million dollars which would be jeopardized by serious pollution of the adjoining waters. The ferries carries during 1903 something over 200,000,000 passengers of whom nearly 9,000,000 crossed the centre of the Upper bay. These passengers are entitled to have their trip kept free from an offensive condition of the harbor waters which will unquestionably develop in time, if the present rate of increase in sewage flow continues and should be added to by the full proposed discharge from the Passaic Valley trunk sewer. The nearest precedent to the construction of such a sewer as is proposed by the State of New Jersey, and the discharge of sewage at either one or several points near together is from the system of the city of Boston and metropolitan districts adjoining, where a discharge at Deer Island in Boston harbor of about 40,000,000 gallons of sewage per day causes the waters about the outlet to be discolored over an area of approximately three-quarters of a square mile. At Moon Island, in Boston harbor, a discharge of about 22,000,000 gallons of sewage in less than one hour coming from tidal detention basins discolors about one and one-quarter square miles, fully two-thirds of this area being offensive to both sight and smell. It seems possible that the sewage from the proposed outfall of the Passaic Valley trunk sewer would discolor and render more or less offensive, well towards five square miles of the most beautiful and most traveled part of New York bay, covering the water on calm days at least, with "sleek" or a thin film of grease, which might extend to Liberty, Ellis and Governors Islands and at times even as far as the Battery, Brooklyn and much of the north and easterly shores of Staten Island.

21 Legislative and Reported History of the New Jersey Project.

Chapter 7 of the Laws of 1896 of the State of New Jersey was entitled "An act for the consideration of the general system of sewage disposal for the valley of the Passaic river and prevention of the pollution thereof."

This law provided for the appointment by the Governor of three citizens of New Jersey to consider the general project. Ten thousand dollars were appropriated to defray the expenses of their investigations.

The report of the commission subsequently appointed by Governor Griggs was submitted to the Legislature Feb. 26, 1897, and included the individual reports of the engineer, chemist, bacteriologist, and secretary, with conclusions and recommendations, including the draft of "An act providing for the purification of the rivers and streams of water within this State (New Jersey) and prevent the pollution of the same."

The Legislature on March 24, 1897, passed an act, becoming chapter 35 of the Laws of 1897, to prevent the wilful pollution of the Passaic river and the tributaries thereof, above the Great Falls of the

Passaic River at Paterson; said act being evidently intended rather to protect the purity of the water supply controlled by the East Jersey Water Company than to reduce the pollution in the lower Passaic Valley.

The report of the commission of 1896 above referred to, did not result in the passage of the law desired, but did result in the passage of an act authorizing a committee of members of the Legislature to study the subject and report at the next session. Various public hearings were held, and in the spring of 1898 the committee
22 reported as a result of its labors that the whole matter ought to be again studied by a new commission, which commission was duly appointed by Governor Vorhees.

The Legislature of 1899 again took up the matter and passed a bill, forming chapter 210 of the Laws of 1899, entitled, "An act to prevent the pollution of the waters in this State (New Jersey) by the establishment of a State Sewerage Commission, authorizing the creation of sewerage districts and district sewerage boards and prescribing and regulating the duties and powers of such commission and such boards." The sum of $5,000 was appropriated for expenses. It may be noted that the functions of this State sewerage commission are general and are not confined to the Passaic Valley solely. This commission has filed several annual reports, viz., for the years 1899, 1900, 1901, and 1902. As a result of their recommendation a law was passed giving additional powers to the commission, by which it could compel the abatement of existing nuisances of certain classes, and authorizing two or more municipalities to cooperate in providing for sewer systems and sewage disposal plants.

In 1900 the Legislature amended the original law, establishing the State Commission, reenacting it as chapter 72 of the Laws of 1900, giving rather broader powers. In 1902 the Legislature passed an act (chapter 48 of the Laws of 1902) establishing a separate sewerage district for the Passaic Valley, and creating a special commission therefor. The State commission since then has been enabled to devote its energies to other localities. The same Legislature also passed an act, becoming chapter 49, providing for the creation and incorporation of sewerage and drainage districts, for each of which the Governor could appoint a commission of five residents of such sewerage district.

23 Under the two laws just referred to, the "Passaic Valley Sewerage District" was created and a commission of five members appointed. This commission organized April 22, 1902, and selected a chief engineer. It submitted its first report to the Legislature on January 23, 1903, containing the report of its chief engineer and a draft of a proposed bill which would more thoroughly provide for carrying out the improvements recommended than possible under existing laws. The studies included two alternative general plans: First, a system of intercepting sewers extending from Paterson to Newark bay, by which the sewage of the valley would be brought to and discharged into the waters of upper New York bay without preliminary purification; second, a similar system of intercepting sewers, but in place of crude disposal, to construct one

or more purification plants where the sewage would first be treated and the purified effluent discharged into the Passaic river or Newark bay. The former plan was recommended by the chief engineer, and is the plan adopted by the Passaic Valley District Sewerage Commission for execution.

It comprises a main interceptor extending from a point near the Great Falls of the Passaic, in the city of Paterson, along the right or westerly bank of the Passaic river to a point in the city of Newark, where it leaves the river and passes southeasterly through the city, across the salt meadows to a point on the shore of Newark bay, about opposite West Bergen Point, where a main pumping station is to be located. From the pumping station the sewage is to be forced through two steel force mains (six feet each in diameter) under Newark bay and up into a gravity sewer thirteen feet in diameter, leading southeasterly along the Morris and Essex canal to a point jutting out into upper New York bay near Pamrapo; from
24 whence the sewage would pass through an eight foot steel pipe leading under New York bay, to a point about three-quarters of a mile northeast of Robbins reef light and opening out in a depth of water of about forty feet below mean low tide.

The Legislature of 1903 passed an act on April 22, modifying somewhat the provisions of the law, to effect, that before any work should be undertaken or obligations incurred, the Passaic Valley Sewerage Commission should investigate whether the proposed discharge of sewage into New York bay is likely to pollute the waters of said bay to such an extent or to such a degree as to create a nuisance to persons or property within the State of New York; and that no work should be carried out until after such investigation had been made and report presented thereon, and until the Attorney-General should in writing advise that no cause of action, either for damage or injunction, would arise in favor of the State of New York or any of its inhabitants by reason of said proposed discharge of sewage.

On June 8, 1903, such special report was submitted giving the opinion of the commission that such discharge of sewage would not pollute the waters of New York bay to such an extent or to such a degree as to cause a nuisance to persons or property within the State of New York; the conclusions of the commission being largely based upon written opinions received from a number of well-known engineers. Governor Murphy having examined the special report, referred it to the State Attorney-General for legal opinion, who advised that in his opinion there would be no legal objection from the authorities of New York. The Governor thereupon authorized the sewer commission to proceed to the construction of the improvements contemplated, and the Supreme Court upon certiorari proceedings upheld the constitutionality of the act. Prior to the report
25 above mentioned the Legislature of the State of New York authorized the appointment of the New York Bay Pollution Commission, which is now filing its report, objections and recommendations.

On March 6, 1905, the Court of Errors and Appeals of the State

of New Jersey declared unconstitutional the act of 1903, under which the Passaic Valley District Sewerage Commission proposed to construct its great trunk system and empty the sewage into New York bay; ten judges being in favor of reversing the Supreme Court which had declared the act constitutional, and but one judge upholding said court. The fatal defect was held to be the method provided for levying taxes to meet the cost of construction and maintenance. Consequently, the immediate threatened danger from the special sewerage system, which caused the appointment of this commission, is delayed by this decision of the New Jersey judiciary. Undoubtedly, however, there will be renewed attempts to pass an act which will avoid the defects of the former ones, so that New York State should continue to take cognizance of this question, and the greater one of general pollution of the harbor as well.

Possible Ocean Disposal of All Sewerage Wastes.

The waters of New York harbor and vicinity are invaluable to the inhabitants of the metropolitan district in their facilitation of New York's enormous commerce, the fact being well established that water communication is far more economical and convenient than land systems. In the relation of the waters to climatic and sanitary conditions the value is also beyond computation, in tempering both heat of the summer and the cold of the winter; and in carrying off or assimilating a large portion of the waste products of civilization which inevitably reach them even when sewers
26 can be made to carry a large part of the wastes to distant points. Probably over a million persons from the district cross these waters at many points daily in going between their homes and their places of business.

While a great deal has been done in the way of caring for urban waste in the final disposal of garbage and purification of sewage, no practical steps have as yet been taken in the metropolitan district towards relieving the district entirely from the sewage being poured into the waters of the harbor by the hundreds of millions of gallons daily. The only consideration that has been given as a rule, has been to conduct the sewage by the cheapest possible route and means to tidal waters, practically regardless of the effect upon them. But two real systems of ultimate final disposal are open to the district as a whole,—one, improved sewage disposal plants for each local district or municipality, established within its own boundaries, which plants would so treat the sewage as to make the effluent innocuous and inoffensive when it reaches the waters of the harbor, the solids being removed or destroyed; the other, the carrying out of some comprehensive scheme for ocean disposal of the crude sewage from the whole metropolitan district lying in New York and New Jersey either by one or by several great trunk sewers or tunnels.

A work of such magnitude can only be suggested at this time in the barest outline, as studies and plans would need to be exceedingly exhaustive and in great detail in order to properly conserve the sanitary and financial interests of the districts affected.

In general the conclusions of the commission would seem to be that owing to the nature of the development of New York city
27 and its environs, the first plan of separate utilization plans would be practically impossible of execution. Therefore, the other plan of ultimate ocean disposal seems to offer the most promising possible solution of the whole question, and one worthy of the fullest and most thorough investigation and development.

Needs of the Whole District and Desirability of Joint State Action.

The commission, from the very inception of its investigations, has been confronted with the fact that the construction of the proposed Passaic Valley sewer is only one of many similar problems demanding legislative action for the protection of the waters of New York bay sewage contamination.

The contention of the New Jersey commission that because the bay is now more or less directly receiving raw sewage from 4,000,000 people, therefore an increase from 1,000,000 more should be permitted is untenable.

The harbor is now an immense cesspool, which like smaller receptacles of sewage, has a natural limit of capacity, beyond which lies the danger to the health and comfort of the contiguous metropolitan district. The residents of New Jersey, who thus expected to discharge their waste through the proposed sewer, are equally interested with the inhabitants of New York city in preserving the waters of the harbor from further contamination.

The establishment of a metropolitan sewerage district has been suggested, to include all sections in both New York State and New Jersey which now or in future might sewer into the bay and its tributaries. Such a district, when authorized by joint State and federal legislation, should be under the direction and control of a permanent interstate commission, with plenary power to
28 control the discharge of all sewers hereafter constructed, as well as the evolving of a comprehensive plan for ultimately rendering the present chaotic and systemless method of sewage disposal, sanitary and suitable for all future requirements.

The necessity already exists for a central authority to not only direct, but also initiate such great public works, upon which depend the beauty and healthfulness of the approximately 450 miles of shore within the metropolitan district.

Legal Status of New York's Jurisdiction Over the Harbor Waters.

Certain questions were presented to State Attorney-General Cunneen from whose replies, abstracts are herein presented (the full answers in Appendix 6).

1. What is the status of the waters of New York harbor as to control over pollution, by the Federal Government and by the two States of New York and New Jersey?

Answer. In the year 1833 an agreement was entered into between these two States, subsequently ratified by their Legislatures and

approved by Congress, which established the common boundary line and which conceded to New York the exclusive jurisdiction of, and over, all waters of the bay of New York, and of, and over, all the waters of the Hudson river lying west of Manhattan Island and southward from Spuyten Duyvil creek, to low water mark on the westerly or New Jersey side thereof, subject to rights of property and of jurisdiction over the same by the State of New Jersey, from the joint boundary line westward and northward respectively; except that vessels even tied to New Jersey docks should be subject to the quarantine or health laws and laws in relation to passengers in the State of New York as they then existed or that might thereafter be passed. The right of regulating fisheries to the westward of the joint boundary line was reserved to the State of New Jersey.

The New York Court of Appeals in one of its decisions deduced a rule which indicated that New York had the right under the agreement to enforce quarantine and sanitary laws over all the waters of New York harbor as described, though both States could retain their absolute control over land under water and docks, vessels or other floating craft attached to any wharf or pier, as far as property rights were concerned; or violation of laws other than those offences against New York quarantine or health laws.

2. Whether the Federal Government would have jurisdiction over any phase of construction and operation of a large proposed trunk sewer to empty into the waters of New York harbor?

Answer. Federal jurisdiction is concerned specially with interference with navigation; consequently if the Passaic Valley trunk sewer should be so constructed as to interfere with navigation, or should its construction and operation be likely to so interfere, the Federal Government would undoubtedly have the right to interpose objection through an action brought in the Supreme Court of the United States. Such action was unchallenged by the State of Missouri against the State of Illinois and the sanitary district of Chicago, concerning the construction and operation of the Chicago drainage canal which proposed to carry sewage from the city of Chicago through a canal and the Illinois river to the Mississippi river. The bill in the action was demurred to, but the court sustained the right of the State of Missouri to maintain its proceedings, based on the sanitary features of the case. Consequently the Federal Government, as represented by the Supreme Court of the United States, would seem to have jurisdiction, not alone on the score of interference with navigation, but to recognize an action brought by the State of New York, in said court, to compel the State of New Jersey and the Passaic Valley District Sewerage Commission to refrain from polluting the waters of New York harbor with so great a mass of sewage as that contemplated, on sanitary grounds.

3. What power, if any, has the State of New York to impose conditions upon the State of New Jersey as to constructing the proposed sewer and to operating it in future?

Answer. The State of New York could only force action or non-

action by the State of New Jersey by proceedings brought before the Supreme Court of the United States.

4. Whether the New York Bay Pollution Commission is authorized by law to suggest detailed plans for any changes in construction of the New Jersey sewer if same is to discharge into the waters of New York bay, and objection be made to the present plans as formulated by the New Jersey Commission?

Answer. There seems to be no objection to the New York Commission making suggestions and recommendations to the New Jersey Commission, though such suggestions could not be enforced.

5. Whether in the event this commission finds it desirable to recommend for future consideration the establishment of a metropolitan district covering parts of the two States of New York and New Jersey, the Legislatures of the two States have authority to establish such district and appoint a commission having adequate powers of administration?

Answer. The legislatures of the two States could undoubtedly establish in each State respectively, a certain district to
31 adjoin a similar district in the other state, and give jurisdiction thereover, to the courts of one or the other of said two States as to all matters pertaining to the sewerage of said district; but it would seem desirable that such possible concurrent acts of the Legislatures of the States of New York and New Jersey should be first approved and ratified by an act of Congress.

Conclusions and Recommendations.

Based upon the commission's own researches during the past eighteen months, and judging from the experiences of other localities, so far as conditions are similar, together with reports along allied lines by other investigators, the New York Bay Pollution Commission concludes as follows:

1. It unhesitatingly protests against the consummation of the present plan of construction as outlined by the Passaic Valley District Sewerage Commission.

2. It recommends that the Legislature authorize the Governor of the State of New York to appoint a Metropolitan District Sewerage Commission. This commission should continue similar examinations to those conducted by the New York Bay Pollution Commission and should thoroughly investigate the questions from engineering and economic standpoints, and make preliminary surveys for, and estimates of cost of, a comprehensive system, for ocean disposal of the sewage of the whole or the greater portion of the districts in both New York and New Jersey which are naturally tributary to New York Bay and adjacent waters. Such act of authorization should include a request that the State of New Jersey appoint a similar commission to work conjointly with that representing New York; the two commissions to cooperate in the investigations and
32 recommendations as to a comprehensive scheme of ocean disposal for the district and to outline a course of procedure for later authoritative action by the two States respectively

and the Congress of the United States. This commission ought to be provided with adequate funds for examinations, surveys, analyses, plans, etc.,—form for such bill presented herewith as Appendix 8.

In the event of the State of New Jersey pressing the construction of the proposed Passaic Valley sewer as planned, if such be authorized by constitutional legislation, the commission would recommend:

3. That the Attorney-General of the State of New York be authorized and directed to bring an action in the Supreme Court of the United States against the State of New Jersey and the Passaic Valley District Sewerage Commission, upon his attention being called to any act of said State of New Jersey, or said sewerage commission, towards carrying into effect the construction of said proposed sewerage system.

In closing, the New York Bay Pollution Commission wishes to express its thanks to the many (Appendix 11) who have been of assistance to it in freely giving of their time and data, and to the few whom the commission has retained for special services, which have been rendered in fuller measure than the direct recompense alone could have required.

Respectfully submitted,

DANIEL LEWIS, *Chairman;*
OLIN H. LANDRETH,
GEORGE A. SOPER,
MYRON S. FALK,
LOUIS L. TRIBUS, *Secretary,*
Commissioners.

March 31, 1905.

33

APPENDIX 1.

Tidal and River Flow.

By Commissioner Myron S. Falk.

It is impossible to obtain exact figures concerning the tidal flow phenomena of the lower Hudson river and New York Bay, but it is probable that a quantity of water not far from twelve to thirteen billion cubic feet enters the upper bay with each tide. Of this quantity, the relative proportions may be taken as follows:

4,250 million cubic feet passing into the East river.
6,750 million cubic feet passing up the Hudson river.
1,750 million cubic feet passing into Kill von Kull.

12,750 million cubic feet total.

These figures are of interest when taken in connection with the areas of the various tidal basins. The tidal area of the Passaic and Hackensack rivers, Newark bay and Kill von Kull comprises about

14.2 square miles. The tidal area of the upper bay is 21.6 square miles, and that of the East River 4.5 square miles; that of the Hudson river can be estimated only with difficulty as the tidal action is noticed at different periods of the year nearly all of the way to Albany.

Path of the Ebb Tide.

The ebb tide coming down the Hudson meets the ebb tide coming eastward out of the Kill von Kull, and both reach in and strike Staten Island between Stapleton and Clifton at a point dis-
34 tant about three to four miles from Robbins Reef light. The tide, then, makes along the shore and traveling along the beach makes Fort Wadesworth. At the same time there is also an ebb coming from the Arthur Kill and Raritan river which, striking the main tide from the Narrows tends to throw it to the eastward again. In calm weather the force of the main tide through the Narrows may reach as far as Swinburne Island and Orchard Shoal, although all winds tend to deflect the current.

Path of the Flood Tide.

The first effect of the flood tide through the Narrows is to strike the shore of Staten Island a little north of the point where the first effect of the ebb is felt; the second effect of the flood is to strike into the flats of the upper bay and to the west of Robbins Reef; the third, is to flow into the Kill von Kull; and the fourth and final effect is to flow up the Hudson river. After the first action of the flood is felt, the tide also travels up on the Brooklyn side of the bay. It is probable that in calm weather the maximum effect of the flood tide is felt on the northwest side of the bay.

General Facts.

The tidal ebb is detected five or six miles from the outer face of the bar, sometimes even outside of Sandy Hook lightship, but there rarely seems to be any concentration of its effects. As gathered from the Government reports, the maximum ebb velocity of the current at the Narrows is 1.5 knots, and the maximum flood 1.2 knots. In the Hudson off Thirty-ninth street these figures are respectively 2.7 and 2.0 knots, and in the East river off Twenty-third street 2.0 and 1.8 knots. Estimating a constant velocity of discharge
35 during the various tidal periods of the day the average ebb velocity at the Narrows would reduce to 1.61 miles per hour; the average flood velocity to 1.48 miles per hour.

The following figures furnish data upon which may be based the computations for determining the dilution of sewage emptying into New York bay or its vicinity; they are taken from the Report of the United States Coast and Geodetic survey for 1886, (page 36):

TABLE I.

Epitome of Results for Discharge.

June 25, 1886.

	Cubic feet.
East river (Nineteenth street):	
Ebb (westerly)	4,454,937,257
Flood (easterly)	4,007,175,676
Excess of ebb	447,761,581
Hudson river (Thirty-ninth street):	
Ebb (southerly)	6,996,678,413
Flood (northerly	6,225,985,545
Excess of ebb	770,692,868
Kill von Kull (West New Brighton):	
Ebb (toward the harbor)	1,790,103,372
Flood	1,712,415,362
Excess of ebb	77,688,010
Narrows:	
Ebb (seaward)	13,819,895,144
Flood	12,703,616,481
Excess of ebb	1,116,278,663

86 It would seem that a verification of the above results might be obtained by finding the sum of the products obtained by multiplying the area of each tidal basin, by the mean rise of the tide in said basin; the following figures furnish such a check. The computations were made in 1884, and have been taken from papers on file in the office of Col. Chas. R. Suter, Corps of Engineers, Army Building, New York City.

TABLE II.

	Tidal area in square feet.	Tidal area in square miles.	Mean range of tide in feet.	Tidal prism in cubic feet.
Upper Bay	601,824,505	21.6	4.4	2,888,757,624
Kill von Kull	68,072,219	2.4	4.6	313,132,206
Newark Bay	235,484,775	8.5	4.8	1,130,326,920
Passaic River	26,446,126	0.95	4.6	121,652,179
Hackensack River	66,765,580	2.4	4.8	320,474,786
East River (to Hell Gate)	126,309,810	4.5	4.4	555,763,164
Total				5,330,106,879

It is proper to note that in this table the northern boundary of the Upper bay is given by a line drawn from the most southerly point of New York City across the mouths of the Hudson and East rivers to the nearest point of land on the opposite shores; the western boundary by a line drawn from Constables Point across the Kill von Kull to the nearest point of Staten Island shore, and the southern boundary by a line drawn across the Narrows, from Ft. Tompkins light to the nearest point of Staten Island shore. It is not stated, from the papers on file, whether these areas are measured to the bulkhead lines or pier head lines of that time; this will cause no material error, however, even if these lines should have suffered change.

There must also be added to the total amount of tidal prism of Table II, the tidal prism of the Hudson river. The tidal area of the Hudson river, from its mouth to Poughkeepsie, comprises 2,-518,740,000 square feet; from its mouth to the State Dam at
37 Albany 3,789,820,000 square feet; but since the average tidal rise is rather difficult to obtain, as the Hudson is occupied by two tides at one time in different portions of its length, the following figures are believed to furnish sufficiently accurate results.

From the Coast Survey Report of 1858 (page 118), the discharge at the

Close of wet season (June 1)	6,038,000,000 cu. feet.
Close of dry season (September)	3,360,000,000 cu. feet.
Mean	4,699,000,000 cu. feet.

From observations from the same source in October, 1872, the flow (found nearly equal for "in" or "out" flow) was found to be 4,511,000,000 cubic feet and from Table I, above quoted, the ebb flow was found to be 6,997,000,000 cubic feet, and the flood 6,226,-000,000 cubic feet. An average of 5,000,000,000 cubic feet is probably correct and would correspond to an average rise of the tide between New York and Poughkeepsie of about 2 feet.

By adding these 5,000,000,000 cubic feet to the total of Table II, a reasonable check is furnished to the figures of Table I (assuming in Table II no entry of water into Newark bay, etc., by way of the kills).

It seems proper, then, to estimate the quantity of water which enters the bay with each tide at between 12 to 13,000,000,000 cubic feet. How much of this is available for the dilution of the sewage to be emptied into the bay at one point by the State of New Jersey, is questionable.

The following figures relating to the fresh water discharge of the Hudson river, were found in Col. Suter's office; they are believed to have considerable value:

Area drained into lower New York bay..... 16.335 square miles
Average rain fall per year at Albany..... 38.73 inches

38

Average rain fall per year at Ft. Hamilton... 39.57
Average rain fall per year at Ft. Columbus... 43.32 } 41.923 inches
Average rain fall per year at New York city... 42.88

Area affected by Albany gauge..... 11,410 square miles
Area affected by mean New York gauge..... 4,925 square miles

Rain fall per second, Albany area..... 32,555 cubic feet
Rain fall per second, New York area..... 15,210 cubic feet

Total Albany and New York areas..... 47,765 cubic feet

Assuming five-tenths of this drained into lower New York bay, furnishes 23,883 cubic feet per second, or, 1,031,745,600 per twelve hours. Any other ratio than five-tenths, could easily be used.

The following data, relating to the timing of currents, has been taken from Bulletin No. 8, Second Edition, U. S. Coast and Geodetic Survey.

Currents—New York Bay and Harbor.

Subject.	Location. Narrows.
Time of high-water slack after high-water at Sandy Hook	Hr. Min. 2 00
Duration of slack	Min. 15 to 30
Time of maximum ebb after high-water at Sandy Hook	Hr. Min. 4 30
Maximum ebb velocity	Knots. 1.5
Time of low-water slack after low-water at Sandy Hook	Hr. Min. 2 30
Duration of slack	Min. 15 to 30
Time of maximum flood after low-water at Sandy Hook	Hr. Min 5 12
Maximum flood velocity	Knots. 1.2

Remark.

In the Narrows both the ebb and flood currents appear first on the east side.

Subject.	Location. Hudson River off 39th street.	East River off 23d street.	East River off Old Ferry Point.
Time of high-water slack after high-water at Governors Island	Hr. Min. 3 08	Hr. Min. 1 54	Hr. Min. 1 16
Duration of slack	Min. 40 to 55	Min. 4 to 8	Min. 20
Time of maximum ebb after high-water at Governors Island	Hr. Min. 6 17	Hr. Min. 4 30	Hr. Min. 4 14
Maximum ebb velocity	Knots. 2.7	Knots. 2.0	Knots. 1.4
Time of low-water slack after low-water at Governors Island	Hr. Min. 3 03	Hr. Min 1 37	Hr. Min. 1 02
Duration of slack	Min. 35	Min. 4 to 8	Min. 18
Time of maximum flood after low-water at Governors Island	Hr. Min. 5 43	Hr. Min. 4 24	Hr. Min. 2 42
Maximum flood velocity	Knots. 2.0	Knots. 1.8	Knots. 1.6

Remark.

In the path of the Hudson, from the Narrows to the Tappan Sea, it is running flood 15 feet below the surface fully an hour before the turning from ebb to flood at the surface.

39 The following table, relating to direction and velocity of currents in New York bay and harbor, has been taken from Bulletin No. 3, (1888) U. S. Coast and Geodetic Survey, page 8.

Lunar hour.	Sandy Hook Bar.	The Narrows.	Kill von Kull.	Hudson River, 42d street.	East River, 10th street.	East River, Old Ferry Point.

S. signifies South.

Currents.

To determine exactly the motion of the water in the bay, it would be necessary to measure velocities of flow, not only at sections separated by horizontal distances, but also at sections separated by vertical distances; furthermore, such observations would be necessary for every single stage of the tide, both ebb and flood. As far as the writer knows, complete investigations of this kind have never been made, although the U. S. Coast and Geodetic Survey reports* contain tables showing velocities measured either along horizontal or vertical lines,
40 but not along both at the same time. Of these measurements, moreover, none is later than 1888, and various building operations occurring since that time, such as the cutting through of the Harlem ship canal, building of piers, etc., would probably render those results of comparatively little value. It seems, therefore, ad-

* See Appendix 8, report for 1871.
See Appendix 10, report for 1876.
See Appendix 15, report for 1887.

visable, except for the preceding general tables, to appeal to the personal opinions of men familiar with those matters.

The general average velocity of the currents is easily obtained; it is necessary only to divide the ebb or flood flow by the cross-section of the corresponding channel. For instance, the area of cross-section at the Narrows is 271,480 square feet; the average ebb velocity, using the figures of Table I, would then be 1.61 miles per hour, assuming that the ebb discharge for six hours would be constant; similarly, the flood velocity would average 1.48 miles per hour. Since there are times of no velocity, it is evident that the maximum velocities will at times greatly exceed these average velocities.

The cross-section of the Harlem river at Thirty-ninth street, contains approximately 173,000 square feet; the average ebb velocity would then be 1.26 miles per hour, and the flood velocity 1.13 miles per hour.

One matter of considerable importance is the question of the under-run of the salt water below the fresh water of the Hudson. The difference in specific gravity between these two waters may be as high as 2½%, and there is thus an obvious tendency for the salt water to force itself up the river for a considerable distance and to remain stagnant while fresh water follows its way down to the sea.

This tendency is probably more marked at times of low
41 water in the river. It seems proper to consider, then, whether the sewage which is discharged into the salt water may not, at various portions of the year, be stored in the pot-holes and basins of the river.

42 ## Appendix 2.

Present Sewage Pollution in New York Harbor.

By Commissioner Louis L. Tribus.

Having been assigned to the investigation of the present sources of pollution of New York harbor, I would report as follows:

I have consulted with the officials having knowledge concerning, or direct charge of, the sewerage system in each of the boroughs of the city of New York, and each of the municipalities adjoining New York Harbor and its estuaries, from the north side of Yonkers, southward, and have secured from them much of the available information as to the situation of sewers and the estimated outflow therefrom.

Whereas the great majority of sewers emptying into these waters carry both sanitary and storm flow, it may be considered that sanitary or dry weather discharge alone particularly requires our consideration, for its peculiarly polluting influence on the waters of the harbor. While at times of storm there is a great washing into the harbor of street refuse, the dilution is at once so great from the storm flow itself and in general the storms are so infrequent that we scarcely need to consider this amount of material, though

exceedingly filthy in itself, as being a serious menace to health or likely to create a permanent nuisance.

The suspended matters in the sanitary flow alone, however, if weighed dry, probably nearly equal 1,000 tons daily, surely a quantity worth anxious thought.

43 The whole territory for a radius of twenty miles from New York City Hall may be called the New York Metropolitan District, as the interests of practically all portions within that district are nearly identical, the manufacturing establishments, stores, offices and homes of those whose interests center in New York city; consequently, I would use the city's name as indicating the whole district noted, even though many municipalities be included and in two different states.

It may not be generally appreciated that this district is one of the largest manufacturing communities of the world and with variety of products almost beyond enumeration, so that the wastes carried through the sewers are equally diverse in character. It should be noted that practically all wastes other than garbage, rubbish and ashes reach the sewers, being carried thereto and therein by an abundant flow of water. While water in itself is a cleansing element, it is so much more convenient a method for the disposal of wastes than others, that the percentage of wastes is actually increased by its use.

Leaving out of consideration the storm water flow, there remains for the constant daily source of sewage pollution, the water borne house and factory wastes; consequently, the quantity of water used in the community is probably the safest estimate and, in fact, the only estimate which can well be presented, to indicate the amount of daily sewage.

The following table has been prepared showing the communities along the shores of New York harbor, the particular body of water into which their sewers empty, the respective estimated populations as of the year 1904, and the estimated daily discharge of sewage in million gallons, based on water consumption. The sewer outlet outlet numbers refer to numbers which will be found upon the map accompanying the main report of this commission.

44 *Approximate Daily Sanitary Sewage Discharge Into New York Harbor.*

Community.	Discharging into—	Sewer outlets. Numbers on map.	Estimated population.	Sanitary flow in million gallons per 24 hours.
Yonkers	Hudson River	330 to 341	56,000	6
New York (Manhattan)	Hudson River	1 to 53	823,000	82
New York (Manhattan)	Harlem and East Rivers	54 to 158	1,234,000	124
New York (The Bronx)	Harlem and East Rivers	197 to 212	297,000	30
New York (Queens)	East River	213 to 236	147,000	15
New York (Queens)	Jamaica Bay	Not numbered	53,000	5
New York (Brooklyn)	East River	159 to 183	920,000	92
New York (Brooklyn)	Upper Bay	184 to 189	271,000	27
New York (Brooklyn)	Lower Bay	190 to 193	40,000	4
New York (Brooklyn)	Jamaica Bay	194 to 196	122,000	12
New York (Richmond)	Kill von Kull	242 to 260	35,000	4
New York (Richmond)	Upper Bay	261 to 278	20,000	2
New York (Richmond)	Lower Bay	Not numbered	8,000	1
New York (Richmond)	Arthur Kill	239 to 241	12,000	1
W. New York, Weehawken, Union, West Hoboken, Hoboken, Jersey City	Hudson River	279 to 305	334,000	33
Jersey City	Upper Bay	306 to 308	23,000	2
Bayonne	Upper Bay	309 to 311	15,000	1
Bayonne	Kill von Kull	312 to 315	27,000	3
Elizabeth and S. Orange system	Arthur Kill	342 to 347	91,000	9
Perth Amboy	Arthur Kill	316 to 329	22,000	2
Totals			4,550,000	455

In the report of the Passaic Valley District Sewerage Commission as presented to the New Jersey Legislature at its session in 1903, it is stated that the plan of the commission contemplates the ultimate construction of a sewer system which would pour into New York harbor nearly 350,000,000 gallons of sewage per twenty-hour hours, though it is not contemplated to execute the whole plant at present. The population to be provided for is estimated at from over 500,000 now to 1,600,000 ultimately. Taking the estimated proportions of the total sewage to total population, the plan would contemplate a debouchement, as soon as the sewer system could be constructed, of upwards of 100,000,000 gallons per twenty-hour hours.

Another large New Jersey sewerage district, though fortunately not so densely populated, is already draining into Kill von Kull at Elizabeth, taking the watershed to the west and southwest of the Passaic Valley district, and sewering a portion of Eliza-
45 beth, Irvington, Vailsburg, South Orange and West Orange. The estimated flow is, however, comparatively small, being from 5,000,000 to 8,000,000 gallons per twenty-four hours, based on dry weather conditions.

It may be noted that the plan of the Passaic Valley District Sewerage Commission, if carried out, would not introduce into the waters of New York a total flow more than would reach it by the ordinary

present routes, because all of the districts proposed to be relieved by said systems now sewer into adjacent streams which empty in turn into Newark bay, thence into Kill von Kull and Staten Island sound, from which the flow passes into respectively the upper and lower New York bays. The difference is, however, that at present, Newark bay, and to some extent the tributary streams, acts as a great settling basin, so that most of the heavier matters are deposited there and save the main harbor from the task of assimilating them. At present such use of Newark bay is not a very serious inconvenience to many interests, but the time can be readily foreseen when the nuisance there will be very evident and intolerable, but the main question at issue is one of conserving the interests of the greater number, rather than the few.

The cause for alarm in New York and vicinity arises from the proposal to empty this large quantity of sewage at approximately one point near the center of the main harbor. The harbor as a whole may be capable of assimilating a thousand million gallons of sewage per day, if distributed at five hundred scattered points, while the same harbor might not be able to assimilate one-tenth the quantity, if poured in at five points, and the nuisance would then become not merely local, but general, as the pool of raw sewage would travel to distant points carried by tide and wind.

46 Upon others of the commission devolves reporting on such of this question. I would, therefore, report in summary that the present direct daily sewage pollution of New York harbor and its estuaries from all existing sewers is taken to be 455,000,000 gallons from something over 4,500,000 population, with probably from 50,000,000 to 100,000,000 gallons more entering through Newark bay.

47 APPENDIX 3.

Sanitary and Bacteriological Examinations and Fisheries and Industries Affected by Pollution of New York Harbor.

By Commissioner George A. Soper.

The question as to the quality of the water and shellfish of the harbor was one which had to be studied largely by means of analyses, while that relating to the industries required the collection of statistical data and information from those who had moneyed interests connected with the bay.

No attempt was made to make the examination of the waters and shellfish exhaustive, although a comprehensive plan for determining the quality of the water in all parts of the bay and rivers in the neighborhood of New York would doubtless have produced results which would have been of much scientific interest. Owing to the small appropriation which was available for the analyses, only the simplest methods could be used and the number of analyses had to be kept as low as possible.

The value of this study of the quality of the water of the bay had been greatly increased by the fact that results of analyses which have been made for others, of the water of the Hudson river and certain other waters, have recently been published in official reports. Among these reports may be mentioned the report of the commission on an additional water supply for the city of New York, 1903; the report of the committee on the Charles river dam, Boston, 1903; the report of the Massachusetts State Board of Health upon the discharge of sewage into Boston harbor, 1900;
48 and the report of the Metropolitan Sewerage Commission upon a high level gravity sewer for the relief of the Charles and Neponset river valley, 1899. Some older documents relating to New York bay have also been useful, notably, Appendix 15, of the U. S. Coast and Geodetic Survey and a pamphlet issued by the Chamber of Commerce of the State of New York on the harbor of New York; its condition, May, 1873.

Accurate information concerning the industries which might be affected by pollution of the bay have been difficult to obtain, reliable statistics being lacking in some cases and estimates made by the Government, State and local authorities differing materially. Wherever it was not possible to reconcile the figures, the most conservative data have been adopted. Information of a statistical character relating to the industries of the bay has been courteously furnished by the U. S. Census Bureau, the U. S. Commission on Fish and Fisheries, the U. S. Steamboat Inspection Service, Bureau of Shell Fisheries of the Forest, Fish and Game Commission of New York State and by many private persons connected with the oyster and transportation business in the vicinity of New York. It is a pleasure to make acknowledgment here of the many favors received from these and other sources.

3—Present Chemical and Bacteriological Condition of the Harbor and Fisheries.

A—Bacterial Evidence of Pollution:—Water.

The bacterial analyses made by the commission, although not numerous, show that the water of the bay is polluted to an extent which, though not great, is at least measurable. About 50 samples of water were taken from the bay at many points between
49 the Battery and Coney Island on the one hand, and the Battery and Raritan bay on the other. These were analyzed with the result that the colon bacillus, an invariable accompaniment of sewage, was nearly always found according to the "presumptive" test.

For the purpose of the analyses, the water was collected in prepared and sterilized bottles by a person trained in such work. After filling, the bottles were immediately carried to the Mt. Prospect Laboratory, Brooklyn, and were examined, as a rule, within two hours of the time when they were collected. In the examinations for the bacillus coli communis, specimens of the water measuring

.1 cubic centimeter, 1 c. c. and 10 c. c. were taken from the bottles and mixed with fermentation broth in Smith tubes, substantially as indicated in the report of the State Board of Health of New York for 1892, p. 712. These tubes were then incubated at 37 deg. C., for 48 hours, or in case of negative results, longer. If colon bacilli were present, they would form gas which would then be analyzed. All of the laboratory work was done under the personal supervision of Mr. Daniel D. Jackson, sanitary chemist and biologist, except a few specimens which were shipped to the Bender Hygienic Laboratory, where they were examined under the supervision of Dr. R. M. Pearce, director.

Some of the samples of water which were sent to the laboratory in Brooklyn were examined for the number of bacteria of all kinds which they contained. The medium used for this bacterial work was nutrient gelatin, prepared according to the methods recommended by the laboratory section of the American Public
50 Health Association, and customarily employed by the analysts of the Department of Water, Gas and Electricity of the city of New York. All of this laboratory work was done in duplicate.

When the colon bacillus was believed to be present, the result of the examination was reported as plus, or simply +. When no evidence of this germ was found the result was reported as negative, or, for convenience, 0.

In interpreting the results, presumptive evidence of the presence of the colon bacillus in each of the three tubes, containing .1 c. c., 1 c. c. and 10 c. c. of water respectively, was taken to be evidence of pollution; no coli in .1 but a positive result with 1 and 10 was taken to mean probable evidence of pollution; coli in neither .1 nor 1, but a positive result with 10 was not regarded as sufficiently significant for any conclusion. These I regard as fairly conservative standards for use under the circumstances.

The following table shows the results which were obtained with the first series of samples taken.

Table 1. Results of examinations of the water of New York bay. The samples were collected along the route of the Iron Steamboat Company, from Pier 1, at the Battery, down the main ship channel of the Upper bay, through the Narrows to Coney Island. The samples were taken between 10 and 11 A. M., on the ebb tide, and between 4 and 5 P. M., on the flood tide. High water occurred at Governor's Island at 5:40 A. M. and 6:07 P. M. The winds were fresh, northeast to south, with a maximum velocity of 17 miles per hour. All of the samples were clear and practically odorless. The date was June 11, 1904.

51

2	South of Liberty Island	28,000	15,600	0	+	+	+	+	+
3	Near Robbins Reef	24,500	16,300	0	0	+	0	+	+
4	Narrows	20,100	8,900	+	+	+	0	0	0
5	Off Gravesend Bay	27,900	12,900	0	+	+	+	+	+
6	South of Sea Gate	7,900	1,810	0	+	+	0	0	0
7	Iron Steamboat Co.'s Pierhead, Coney Island	6,200	1,900	+	+	+	0	+	+

This table shows that the number of bacteria diminished with some regularity from the Battery to Coney Island, excepting in the samples taken off Gravesend bay, where local sources of pollution exist. The tests for coli are less convincing, but indicate an improvement at the Narrows and at Sea Gate over the Upper bay. The fact that coli were more often found at Gravesend and Coney Island than in some places where their presence would be more expected suggests that local sources of contamination exist in these neighborhoods. On the whole the water of the incoming tide better than the water of the outgoing tide.

Analyses of harbor waters were continued in October with the object of learning something of the quality of the water along the Staten Island and Long Island shores and over the oyster beds which are situated along the west shore of the Lower bay. The results of these bacteriological examinations are given in the tables which follow:

Table 2. Results of examinations of water taken from various points between St. George and South Beach, Staten Island. The samples were collected from the ends of piers and docks along the shore, on October 17, 1904, between 12.25 and 3.40 P. M., toward the end of the flood tide, through slack water and the beginning of the ebb. The tide was high at Governor's Island at 2:47 P. M., and at the Narrows 25 minutes earlier. The wind was light, to fresh, 52 with a maximum velocity of 13 miles per hour; in direction, southwest and west.

17	South Beach, middle	6,800	+	+	+

Table 2, when interpreted by the aid of other information, affords an instructive illustration of several matters which are of special importance in this investigation. The north side of Staten Island from the Narrows to St. George is provided with sewerage systems which discharge the sewage of 20,000 people into the waters of the Upper bay along this shore. When the samples of water were taken for examination, the current was running from east to west along the shore carrying an increasing load of sewage with it. This is admirably shown by the analyses, which indicate a decidedly polluted condition of the water of St. George and a progressive reduction in its impurities from this point to the vicinity of the Narrows. The nearest sewer outfall to the Narrows is near where sample 13 was taken, and beyond this point the number of bacteria and prevalence of coli are fairly uniform. The quality of water in the samples from 14 to 17, inclusive, is probably a fair indication of the quality of the water which occupied the Lower bay at the end of the flood tide.

Duplicates of samples 8, 9, 12 and 15 were sent to the Bender Hygienic Laboratory, for analysis. The results reported from this laboratory in connection with these and other samples have not always checked with the results reported by Mr. Jackson, the
53 disparity being accounted for on the assumption that the bacterial character of the waters changed during the three to six days which elapsed between the collection and analysis of the samples in the Bender Laboratory. The laboratory methods were not precisely alike. Instead of using fractional specimens of the water for examination, five Smith tubes were inoculated with 1 c. c. each at the Bender Laboratory. No germs of the coli type *was* found in any of them.

In order to investigate the quality of the water of Gravesend bay samples were collected in that part of the Lower bay on October 20, 1904. Previous analyses indicated that the water in this section was polluted, and as the bay is known to receive the sewage of about 40,000 people, and is used to some extent for the growing of clams and oysters, particular interest attached to the examinations. The results of the analyses are given in table 3.

Table 3. Results of examinations of water taken from various points between Fort Hamilton and Sea Gate, in Gravesend bay. The samples were collected from a boat along shore, October 20, 1904, between 1:45 P. M. and 3:45 P. M., through the middle of a rising tide. The tide was high at Sandy Hook at 4:52 P. M., and at the Narrows at 5:22 P. M. The wind was light to fresh, east to south, with a maximum velocity of 13 miles per hour.

29	Opposite Sea Gate, 200 feet north	8,200	0	0	+
30	Opposite Sea Gate, 500 feet north	8,900	0	0	+

Table 3 indicates that the water along practically the whole shore of Gravesend bay is polluted. More than half the examinations for coli resulted positively, even in samples of water as small as 0.1 of a cubic centimeter. The numbers of bacteria were smaller than would have been expected, in view of the known sources of pollution. The coli results for 20 can hardly represent the average condition of the water at the point named, for it is within but a few feet of a large sewer outfall. Altogether, the samples, although taken along the shore where the contamination ought to be greatest, do not show as much pollution as exists in Gravesend bay. The incoming tide was distinctly favorable to the purity of the samples. It is likely that Table 3 shows the best conditions which ordinarily occur.

In order to obtain a check on the analyses, duplicates of samples 19, 20, 21, 26, 29, and 30 were sent to the Bender Hygienic Laboratory at Albany. No evidence of coli was found in any sample except sample 20. In that case there were germs of the coli type found in one out of the five tubes inoculated.

A final series of samples for bacterial analysis was taken along the east shore of Staten Island on October 22, 1904. The series exhibited in Table 2 carried the observations to the Narrows, on the shore of Staten Island, and the series which is about to be described overlapped this somewhat and extended down the Lower bay to Tottenville, passing the day-summer resorts of Midland Beach and South Beach, and running over the extensive oyster beds which lie along this coast. The results of the examinations of the waters collected over this route are given in Table 4.

Table 4. Results of examinations of water taken from various points between Stapleton dock and a point off Tottenville, Staten Island, October 22, 1904. The samples were collected between 1:00 P. M. and 5:40 P. M. The tide was low at the Narrows at 12:25 and high at Sandy Hook at 6:17 P. M. The results were therefore obtained during a rising tide. There was a brisk west wind, with a maximum velocity of 30 miles per hour.

50	Off Tottenville	59,700	+	+	+

A close study of Table 4, in connection with information concerning the territory over which the samples were taken, leads to the opinion that some of the results were influenced by local sources of pollution. Those at Lemon creek, Nos. 45 and 46, show the effects of drainage which enters that creek from about 2,010 acres of populated country tributary to it. Nos. 48 and 49 and 50 show pollution due to sewage from public sewer outfalls at Tottenville and perhaps more remote points above the Arthur Kill. The other 15 samples were not taken within close range of sewers, so far as is known, and therefore give a better knowledge of the effects of more distant contamination. Considered as a whole, the table may be divided into three parts. The samples from Rosebank to Midland Beach show marked evidence of pollution. From Elm Tree Beacon to beyond Great Kills the water contained but few bacteria and few
56 of the coli type. From south of Great Kills to Tottenville there was generally strong evidence of pollution.

A—Bacterial Evidence of Pollution.—Shellfish.

As will be more fully explained beyond, the cultivation of oysters and clams is carried on extensively in the waters of lower New York bay. Most of the shellfish are taken from the southeast shore of Staten Island, but some, and especially clams, are grown in that portion of the lower harbor known as Gravesend bay. To determine whether the oysters and clams grown in the bay bear any evidence of pollution, specimens of both kinds of shellfish have been collected and examined for bacteria of the coli type by means of the "presumptive" test.

The shellfish were collected by Mr. D. D. Jackson on the same trips on which he collected samples of water reported in Tables 3 and 4. They were collected by opening the shellfish with a sterilized knife and inoculating the liquid contained in the shell in por-

tions of 0.1 c. c., 1.0 c. c. and 10 c. c. in fermentation broth in Smith tubes. The laboratory process was thereafter similar to that followed in the examinations of water. All of the shellfish were taken fresh from the beds, except those from Lemon creek.

Table 5. Results of examinations for B. coli in fifty-one specimens of oysters and clams grown in the waters of lower New York bay.

Point of collection.	Date.	Number of shellfish examined.	Number of Positive Tests for Coli.		
			0.1 c. c.	1.0 c. c.	10 c. c.
Gravesend Bay, Sea Gate...	Oct. 20	6 clams.....	0	0	2
Gravesend Bay, Sea Gate....	Oct. 20	6 oysters.....	1	2	4
Gravesend Bay, Bath Beach..	Oct. 20	5 oysters.....	0	1	2
Off Elm Tree Beacon	Oct. 22	6 oysters.....	1	3	4
Swash Channel	Oct. 22	6 oysters.....	0	0	2
Great Kills	Oct. 22	10 oysters.....	0	0	1
Princes Bay	Oct. 22	6 oysters.....	0	1	2
Princes Bay, "drunk" in Lemon Creek	Oct. 22	6 oysters.....	3	5	6

For the sake of a check, six specimens of oysters from Bath Beach, Gravesend bay, and six from off Elm Tree Beacon were sent to the Bender Hygienic Laboratory, Albany. The oysters were there scrubbed with sterile salt solution and a sterile brush, after which the shell was opened with a sterile knife and the oyster and juice placed in a sterile dish. The meat was then finely divided and the supernatent milky fluid, in samples of 1 c. c. each, inoculated into 2 per cent. glucose broth in Smith tubes. The results of these tests for coli were positive in two of the six oysters from Gravesend bay and positive in five of the six oysters from off Elm Tree Beacon.

Table 5 demonstrates the very important fact that oysters which are grown in polluted water are usually themselves polluted. Yet the samples examined for this study did not always bear as much evidence of this pollution as might be expected. In view of the known pollution of Gravesend bay, a greater number of positive tests for coli might have been looked for there. The results may be explained by the fact that the shellfish in that bay are only cultivated in the least polluted localities. The oyster beds on the Staten Island shore seem to lie between two great sources of danger, one being the polluted water which passes out through the Narrows and the other being the contaminated water from the mouth of the Raritan river and the Arthur Kill. The oysters which were freest from coli came from the vicinity of the Great Kills and Swash channel—points which are well removed from local sources of pollution and apparently beyond the reach of contaminating matters from the cities. The oysters which were "drunk" in Lemon creek bear distinct evidence of the contamination of that creek.

58 B—Chemical Evidence of Pollution—Water.

The chemical analyses which have been made by ourselves and others show that the water bears chemical evidence of pollution both at ebb and flood tide, especially in the upper bay. The examinations do not warrant the opinion that the water is everywhere and at all times badly contaminated, but the chemical evidence well supports the bacterial results in showing that traces of pollution can be found after the sewage has been thoroughly commingled with the waters of the bay and traveled miles from its points of origin.

One of the best measures of pollution at the service of the chemist is the determination of nitrogen in the forms of free and albuminoid ammonia. The test for free ammonia is particularly significant for the reason that free ammonia is always present in sewage, and when found in large amounts in water, is not likely to have been derived from harmless sources.

The following figures showing the amounts of free and albuminoid ammonia which have been found in uncontaminated sea water, drinking water and sewage, are taken from a report of Mr. H. W. Clark, contained in the report of the Metropolitan Sewerage Commission upon a high level sewer for the relief of the Charles and Neponset River valleys, p. 91, a report by Mr. G. C. Whipple, contained in the report of the Commission on an Additional Water Supply for the City of New York, p. 520, and a report by Mr. H. W. Clark contained in the report of the Committee on the Charles River Dam, Boston, p. 221.

Table 6. Results of chemical analyses of sea water. (Parts per million.)

59

Point of collection of sample.	Date.	Free ammonia.	Albuminoid ammonia.	Chlorine.
Sea water	.....	.057	.124	
Quincy Bay, Massachusetts	.....	.056	.124	
Atlantic Ocean, 3 miles southeast of Sandy Hook lightship	Feb. 27, 1903	.064	.076	16.250

	Average			.129	.143	

*100 ft. off.
* "
* "

From this table it appears that the water of the bay contains about 2¾ as much free ammonia, and about 1½ times as much albuminoid ammonia, as pure sea water, and about 6½ times as much free ammonia, and about the same amount of albuminoid ammonia as the Hudson river at Poughkeepsie. Comparing this table with Table 6, it will be seen that the most polluted samples were taken from near the Battery, Robbins Reef, the Narrows and Coney Island. The figures in the last table, excepting those
60 relating to the first three samples, are taken from the report of the Commission on an Additional Water Supply for the City of New York. The same report contains data from which the following table has been made to show the ammonias in the water of the Hudson as far up as Kingston. The figures given are averages of weekly examinations made from February to August, 1903.

Table 8. Results of chemical analyses of water of the Hudson river. (Parts per million.)

Point of collection of sample.	Tide.	Free ammonia.	Albuminoid ammonia.
Newburgh	High...	.019	.126
Newburgh	Low....	.024	.140
Poughkeepsie	High...	.022	.126
Poughkeepsie	Low....	.019	.149
Hyde Park.....	High...	.024	.133
Hyde Park.....	Low....	.036	.153
Kingston	High...	.029	.131
Kingston	Low....	.029	.149
Average.....	.....	.025	.138

These figures show that the water of New York bay, as indicated in Table 7, contains nearly six times as much free ammonia and

about the same amount of albuminoid ammonia as the water of the Hudson between New York and Poughkeepsie.

B—The Effects of Tides, Currents and Other Purifying Agencies.

One of the suprising results of this investigation, as disclosed up to this point, is the fact that the tide has little visible effect in eliminating the evidences of pollution. It had always been assumed that the sewage and other organic impurities which drained into the harbor were carried away by the vast quantities of pure water
61 which came in from the sea, the sound and the Hudson river. But it is here found that there is not a great deal of difference between the quality of the incoming and outgoing currents. In some cases the currents flowing up the bay from the sea have been more polluted than those passing out on the ebb tide. It seems that, in spite of the great tidal movement, particles of sewage which are not destroyed or affected by the wind, pass back and forth indefinitely in the bay and rivers in the neighborhood of their points of origin. The action of the tide seems rather to create a diffusion and distribution of the impurities than a mechanical replacement of them by pure water.

The question of the diffusion of the water of the bay has such an important bearing on the question of the disposal of the sewage which enters it, that I have thought it worth while to collect data to show the proportions of sea water and fresh water in the bay under different circumstances.

A—Proportions of Salt and Fresh Water in New York Bay.

The commingling of the salt and fresh water is well illustrated by the records of analyses of samples of the water taken at various points in and about the harbor. For the purposes of this study the water of the ocean beyond the range of fresh water influence may be taken as averaging about 18,000 parts of chlorine per million, although it varies considerably in different parts of the sea. We may take the chlorine of Long Island sound to be about 14,000, and the Hudson at Poughkeepsie at about 1.5 parts per million.

Table 8. Proportions of salt and fresh water found at several points near the entrance of New York bay. (Chlorine results stated in parts per million.)

62

Point of collection of sample.	Date.	Tide.	Chlorine.	Approximate per cent of sea water.
Atlantic Ocean, 3 miles east of Sandy Hook Lightship	Feb. 27, 1903	Flood.	16,230	90
Opposite Sandy Hook Light	Feb. 26, 1903	Ebb...	14,700	82
Opposite Sandy Hook Light	Feb. 26, 1903	Flood.	15,300	85
Rockaway Bell Buoy	Feb. 27, 1903	Flood.	14,850	82
West Bank Light	Feb. 26, 1903	Ebb...	12,450	69
Coney Island Pier	June 11, 1904	Ebb...	18,180	100

The most striking fact exhibited by this table is the difference between the first five results and the last. The dates were widely separated, and it is probable that the first lot of samples, taken for the Commission on an Additional Water Supply for New York City, were taken after heavy rainfalls which produced freshets in the Hudson, Raritan and other rivers which empty into lower New York bay. The following tables 9 & 10 probably show more accurately the average conditions of saltness in the Lower bay.

Table 9. Proportions of salt and fresh water found along the shore of Staten Island, in the lower New York bay. The samples were collected, beginning with the one at Stapleton dock and proceeding toward Tottenville, from 1:00 P. M. to 5:40 P. M., October 22, 1904. The tide was rising, being low at the Narrows at 12:25 P. M., and high at Sandy Hook at 6:17 P. M. The wind was blowing briskly from the west with a maximum velocity of thirty miles per hour. (Chlorine results are stated in parts per million.)

33	Narrows off Fort Wadsworth	12,050	67
32	Rosebank	12,350	68
31	Stapleton Dock	12,850	71

63 The first part of Table 9 shows the effects of the fresh water which enters the bay from the Raritan and Shrewsbury rivers while the last part shows the freshening effects of the outward flow from the Narrows. The water in the Lower bay beyond these influences was probably about 75% sea water.

The water in Gravesend bay was found to be somewhat less salt than that along the Staten Island shore on a day when the tide and weather permitted a fair comparison to be made between the two.

Table 10. Proportions of salt and fresh water found at several points in Gravesend bay. The samples were taken, beginning at Fort Hamilton and proceeding toward Sea Gate, between 1:45 P. M. and 3:45 P. M., October 20, 1904. The tide was rising, being high at Sandy Hook at 4:52 P. M. and at the Narrows at 5:22 P. M. The wind was light to fresh, east to south, with a maximum velocity of 13 miles per hour. (Chlorine results are stated in parts per million.)

Map No.	Point of collection of sample.	Chlorine.	Approximate per cent of sea water.
30	500 feet north of Sea Gate	12,800	71
29	200 feet north of Sea Gate	12,600	70

20	Fort Hamilton Beach, 100 feet south of East End	13,450	75
19	Fort Hamilton Beach, 100 feet from West End	13,800	77
18	Fort Hamilton, 100 feet south	12,800	17

The water at Gravesend bay on the day when the samples reported in Table 10 were collected ranged from 70% to 77% sea water. The lower figures probably represent the effect of local dilution from Coney Island creek and upper New York bay. On
64 the whole, the salinity is remarkably uniform, the greatest difference being only about 7%.

Table 11. Proportions of salt and fresh water found at various points in the upper New York bay. The results which bear the dates February 26-27, 1903, are taken from the report of the Commission on an Additional Water Supply for the City of New York. The rest are from analyses made for the New York Bay Pollution Commission. (Chlorine results are stated in parts per million.)

In Table 11 it will be seen that the water of the Upper bay was composed of about one-third to three-fourths sea water, the rest

being land water. The proportions evidently depended upon the point where the sample was taken, and usually, to a less extent, upon the stage of the tide. In fact the action of the tide seems to have affected it but little.

But the harbor does not always contain more salt water than fresh. As early as 1856 specific gravity determinations of the water in this vicinity were made by Prof. Henry Mitchell of the
65 United States Geological Survey, and in at least two of these, one from Pier 1, North river, and the other from the Hudson at One Hundred and Fifty-second street, the proportion of sea water was less than 20%. Samples collected March 3, 1903, for the Commission on an Additional Water Supply for New York City, show that the bay on that occasion held much more fresh water than salt. As a result of analyses taken every hour from 8 A. M. to 7 P. M., the following averages were found: The tide was high at Fort Hamilton at 10:12 A. M. and 10:46 P. M.

Table 12. Proportions of salt and fresh water found at several points in upper New York bay, East river and the lower Hudson as shown by the average hourly observations of chlorine, at a time when the Hudson was discharging large quantities of fresh water. (Chlorine results stated in parts per million.)

Point of collection of sample.	Chlorine.	Approximate per cent of sea water.
Narrows	7,862	43
Battery	2,767	15
Hudson at 130th street	267	1
Hudson at Spuyten Duyvil	99.2	.5
Hudson at Alpine	21.3	.1
Hudson at Hastings	15.7	.08
East River at Brooklyn Bridge	7,435	41
East River at Blackwells Island	9,958	55
East River at First avenue	7,727	43
Harlem River at Spuyten Duyvil	433	24

Besides showing how greatly the water in the vicinity of Manhattan may be diluted by the water of the Hudson, Table 12 shows that fresh water backed up the East river, making it fresher as far as Blackwells Island, at least. Beyond that point the reduction in salinity of the Harlem river were plainly felt. Marked differences occurred in the amounts of chlorine found in the samples taken at different hours at the same points, as might
66 be expected where the salt and fresh waters were meeting and mixing actively. At one hour the water at the Narrows was only about one-quarter salt; at the Battery only about one-ninth as salt as the sea, and at One Hundred and Thirty-ninth street and the Hudson it contained only about .14% sea water.

As illustrative of the high degree of salinity which sometimes occurs at the points just mentioned the following table, 13, compiled from data obtained from the same source as the last, is useful. The samples were collected on May 28, 1903, at every hour from 8 A. M. to 7 P. M. The weather had been dry. High water occurred at Fort Hamilton at 8:48 A. M. and 9:13 P. M.

Table 13. Proportions of salt and fresh water found at several points in the Upper New York bay, East river and lower Hudson, as shown by the average of hourly observations of chlorine, at a time when the Hudson was discharging very little fresh water. (Chlorine results stated in parts per million.)

Point of collection of sample.	Chlorine.	Approximate per cent of sea water.
